FIGURE 149-7. Coronal section through the skull at the level of the coronal suture. The needle is visible along its trajectory.

FIGURE 149-8. An alternative method for subdural fluid aspiration. The inset shows the oblique trajectory of the needle into the subdural space.

ALTERNATIVE TECHNIQUES

There are numerous alternatives to the aspiration of the fluid collection. These include burr hole drainage, craniotomy, drainage through an external collecting system, observation, and placement of a subdural-to-peritoneal shunt. Do not perform the aspiration with symptomatic nonliquefied clot or extensive membrane development. Consult a Neurosurgeon to evaluate and manage the patient.

Some Physicians prefer to use an intravenous catheter rather than the spinal needle. Removal of the metal needle leaves a soft catheter in place that minimizes the risk of injury to the brain or intracranial vascular structures. The use of an intravenous catheter set rather than a spinal needle is left to the discretion of the Emergency Physician.

ASSESSMENT

Monitor the child for a change in their level of functioning after subdural aspiration. Comparison to the child's baseline neurologic examination is essential. It is mandatory to document timed serial neurologic examinations in the medical record. The clinical examination is age-related. It is often prudent to observe the infant in the arms of a parent or health care worker while monitoring their level of alertness, extraocular movement, facial expression, limb movement, and pupillary response. Obtain daily head circumference measurements and plot them on a chart. Note the size and feel of the anterior fontanel. Note any signs of infection. **Infection can be prevented with careful attention to aseptic technique.** A simple bandage placed over the puncture site is usually sufficient and can be removed 48 to 72 hours after the procedure. Monitor continued spontaneous drainage through the puncture site as it poses an infectious risk.

AFTERCARE

Perform an ultrasound or CT scan of the head to determine if the fluid collection has been adequately drained.^{10,13} Bedside ultrasonography is an effective tool in neonates and young children. Any change in the child's neurologic examination requires an emergent head CT scan or ultrasonography to determine if the subdural fluid collection has reaccumulated.^{10,13}

Send the aspirated fluid for the appropriate laboratory analysis if an etiology other than an acute traumatic hemorrhage is suspected. This can include a biochemistry analysis (e.g., glucose and protein

level), cell count and differential, culture (e.g., bacterial, fungal, or viral), cytology, and Gram's stain. Admit the child to the Intensive Care Unit where they can be appropriately monitored and observed.

COMPLICATIONS

The primary complication of aspiration of an extra-axial fluid collection in the infant is injury to the superior sagittal sinus or draining veins. This can result in further bleeding, brain compression, and brain herniation. This is best avoided by inserting the spinal needle 2.5 to 3 cm lateral to the midline. **At no time should the trajectory of the needle be in the midline or parasagittal in location to avoid this complication.** Overpenetration of the spinal needle can result in brain or intracerebral hemorrhage. Have an assistant immobilize the child to prevent them from moving and the needle lacerating the brain or a blood vessel.

Persistent leakage of subdural fluid from the puncture site can be the result of insufficient fluid aspiration or failure to use a Z-tract. This complication can be prevented by tunneling the needle under the scalp prior to penetrating the lateral margin of the anterior fontanel (**Figure 149-6**). Leakage can usually be controlled with local pressure, head elevation, and rarely by using cotton soaked with tincture of benzoin or Mastisol. Placement of a single suture at the puncture site will usually control continued leakage if less invasive methods fail.

Introducing infection into the subdural space has been reported following a subdural aspiration.¹⁴ Avoid this by maintaining strict sterile technique. Nervous system disability is the result of the subdural hemorrhage and not the procedure.^{15,16} An infection can make this disability worse.

SUMMARY

Extra-axial fluid collections are common problems during infancy. They are regarded as posttraumatic lesions in the great majority of cases. Birth trauma is sometimes implicated but is not common. It appears that minor injuries during infancy or more violent injuries (e.g., cranial impact and shaking) are the inciting events. It is incumbent upon the Emergency Physician to rule out any possibility of NAT! Report actual or suspected abuse to the appropriate state agency as required by law. Emergent aspiration of extra-axial fluid collections in the symptomatic child can be completed safely with very little risk to the child. Admission and continued observation are mandatory.

Skeletal Traction (Gardner-Wells Tongs) for Cervical Spine Dislocations and Fractures

Thomas Engel and Rebecca Roberts

INTRODUCTION

Traumatic injuries to the cervical spine result from forces acting on the head and neck. The incidence of spinal cord injury in the United States is approximately 5 per 100,000.¹ Approximately 60% to 80% of spinal cord injuries involve the cervical spine. Cervical spine injuries can occur at all ages with predilection for teens and young adults. Emergency Physicians must be aware of cervical spine injuries in the elderly with seemingly minor mechanisms of injury.² Motor vehicle collisions are the most common cause and account for almost half of cervical spine injuries.³ The remaining cervical spine injuries result from falls, sports injuries, violence, penetrating wounds, and miscellaneous causes. Few other injuries have the potential to cause such high levels of morbidity.

The primary aims of therapy with an acute spinal cord injury are to safely extract and transport patients from the scene, to identify injury early, to minimize secondary injury to the spinal cord by preventing hypoxia and hypotension, to realign the spine, to improve neurologic recovery, to maintain spinal stability, and to obtain an early functional recovery. This is achieved by decompression of the spinal cord through restoration of the normal sagittal diameter of the spinal canal using cervical traction and/or removing a compressive lesion surgically. This is particularly important in patients who have sustained an incomplete spinal cord lesion and are found to have a progressing neurologic deficit. Restoring the normal anatomic position provides pain relief.

Consider all cervical spine injuries unstable until proven otherwise. Neurosurgical guidelines recommend the use of a rigid cervical collar with supportive blocks and taping of the patient's forehead to the backboard to provide for the greatest degree of cervical stabilization.⁴ Operative intervention has become more common in the management of cervical trauma with improved imaging and surgical tools. The use of skeletal traction in the acute spinal cord injury patient remains a safe and straightforward method of reducing fractures and maintaining the spinal canal in anatomical

alignment during initial management, as a surgical adjunct, or as definitive therapy.

Fabricius Hildanus utilized forceps in treating fractures or dislocations of the cervical spine as early as 1646. Crutchfield is credited for introducing skeletal tongs in the management of cervical spinal injuries.⁵ Crutchfield developed a pair of self-tightening tongs in 1933 that allowed him to apply traction to the cranium in a patient with a cervical spine fracture.⁵ These tongs were subsequently modified and have essentially been replaced by the Gardner-Wells tongs.⁶ Gardner-Wells tongs were introduced in the early 1970s and utilize the principle of a spring-loaded point for cervical traction.⁶

ANATOMY AND PATHOPHYSIOLOGY

Cervical spinal cord injuries can be divided into upper (i.e., occiput to C3) and lower (i.e., C3 to C7) injuries. Numerous classification systems exist. These are based upon the morphology and the mechanism of injury.⁷ No classification is ideal. **Critical to all cervical spine injury classifications is the determination of the stability of a fracture or dislocation.** Stability of the vertebral column is dependent upon the integrity of the vertebra, the intervertebral disk, the facet joints, and the ligamentous structures.

Clinical stability of the cervical spine is determined by the ability of the spine under physiological loads to maintain its normal anatomic relationship so that there is no damage to the spinal cord or nerve roots. It has been proposed that spinal instability be separated into mechanical, neurologic, and combined types. Mechanical instability implies that the injured spine could collapse or distort under normal physiological stresses. Neurologic instability implies a risk of neural injury (i.e., spinal cord and/or nerve root) subsequent to the initial injury.

It is imperative that a thorough clinical and radiologic evaluation be completed to determine if the patient has suffered an unstable cervical spine injury. Begin with a thorough history and physical examination. Perform a complete neurologic examination with particular attention to spinal cord function. Cervical spine radiography is indicated to evaluate fracture patterns, disk disruption, vertebral subluxation, vertebral dislocation, vertebral angulation, and ligamentous injury. A computed tomography (CT) scan is recommended with possible addition of magnetic resonance imaging (MRI) and myelography if available in a timely fashion and if indicated. The radiograph for ligamentous injury evaluation should look for disruption of each of the major spinal ligaments (i.e., the anterior longitudinal ligament, the apophyseal ligamentous complex, the posterior ligamentous complex, and the posterior longitudinal ligament). Radiologic findings that indicate instability include diastasis of the apophyseal joints, dislocations, disruption of the posterior vertebral bodyline, interspinous process widening, vertebral displacement, and widening of the spinal canal.

White and Punjabi proposed a checklist point value system (Table 150-1).⁸ A point value is assigned to each of the injuries appreciated on the cervical spine radiographs. The total point values are then summated. A score of five or more is suggestive of clinical instability. The indications for the application of the Gardner-Wells tongs includes evidence of cervical spine instability.

The spring-loaded pin design of the Gardner-Wells tongs and tilting of the pins in the direction of pull ensures a firm and prolonged grasp of the skull. Gardner-Wells tongs have the capacity to tolerate at least 65 pounds or more of traction. The amount of weight necessary to accomplish reduction varies considerably. As a rule, 5 pounds of weight is applied for each vertebral level above the level of the fracture or the dislocation. Many authors have recommended the use of up to 50 to 60 pounds of weight.⁹ Others have applied weights in excess of 100 pounds to reduce a cervical subluxation.¹⁰

TABLE 150-1 Checklist for the Diagnosis of Clinical Instability in the Lower Cervical Spine⁸

Element	Point value*
Anterior element destroyed or unable to function	2
Posterior element destroyed or unable to function	2
Relative sagittal plane translation > 3.5 mm	2
Relative sagittal plane rotation > 11°	2
Positive stretch test	2
Spinal cord damage	2
Root damage	1
Abnormal disk narrowing	1
Dangerous loading anticipated	1
Developmentally narrow spinal canal	1

*Summate the points. A total of 5 or more points is considered clinically unstable.

The concern for using an excessive amount of traction weight is overdistraction that can result in a traction type of spinal cord injury. Begin by applying 5 to 10 pounds of weight.³ Add additional weight in 3 to 5 pound increments if the initial application of weights fails to achieve spinal alignment. Obtain lateral cervical spine radiographs 10 to 15 minutes after each addition of weight until the cervical spine is realigned. This time delay is needed after the application of weight to allow the soft tissues to accommodate. **It is of paramount importance to monitor the patient’s neurologic status during the entire procedure to prevent iatrogenic injury from overdistraction of an unstable motion segment.**

INDICATIONS

Neurosurgical or Orthopedic Spine consultation is advised if available. Immediate surgical intervention or placement of a halo device often provides more definitive management, a greater degree of immobilization, and improved outcomes. The definitive management of the cervical spine injury can include skeletal traction with Gardner-Wells tongs if clinical instability is demonstrated or suspected, or if reduction of a displacement (i.e., a dislocation or fracture) is needed and consultant availability is limited or delays in intervention are present.¹¹⁻¹³ Other indications for the application of Gardner-Wells tongs are certain cervical infections or neoplasms, anterior cervical discectomy with graft fusion in which distraction of the disk space is required, cervical spine facet fractures, cervical spine spondyloptosis, and cervical spondylosis.^{14,15} Only apply Gardner-Wells tongs if the patient requires temporary longitudinal traction.¹⁶ Their use requires the patient to remain bedridden as compared to halo vest traction.

CONTRAINDICATIONS

Cervical traction is contraindicated in someone who has sustained posttraumatic disk herniation with spinal cord compression. Perform a good neurologic evaluation, a CT scan, or MRI scan prior to applying cervical traction. Some have advocated for an MRI evaluation prior to all cervical traction due to fears of iatrogenic spinal cord compression from disk herniation. The literature has not shown that time delays due to MRI imaging have proven detrimental to functional recovery.¹⁷ Fractures of the skull and infections overlying the potential pin sites are contraindications to the use of skeletal traction. Other contraindications include diseased bone and children less than 3 years of age. Atlantooccipital dislocations and C1-C2 dislocations are contraindications as applying Gardner-Wells tongs to someone who survives these injuries could worsen the patient’s condition and/or neurologic deficit.

FIGURE 150-1. The Gardner-Wells tongs. (Photo courtesy of Eric F. Reichman, PhD, MD.)

EQUIPMENT

- Skin prep kit
- Hair clippers
- Povidone iodine solution, chlorhexidine may damage nerve tissue
- 1% or 2% lidocaine with epinephrine
- 5 mL syringe
- 18 gauge needles
- 22 gauge needles
- Gardner-Wells traction tongs
- Pulley traction system
- Traction weights, 3 to 5 pound increments
- Topical antibiotic ointment

The Gardner-Wells tongs are a simple device (**Figure 150-1**). It consists of a contoured and rigid stainless steel rod that follows the coronal contour of the calvarium. Gardner-Wells tongs are available in versions composed of graphite or titanium alloy. These versions are compatible with and facilitate subsequent CT and MRI scans without producing artefacts. The Gardner-Wells tongs have a threaded hole on each end that accommodates the pins. The spring-loaded pins are threaded screws with sharp cone-shaped points. One of the pins is the calibration pin (**Figure 150-2**). It contains an indicator pin that extends and retracts as the tip of the calibration pin penetrates the skull. The pins screw into the rigid rod so that the points are tilted in the direction of the pull. This results in the pins pressing into the skull when traction is applied and ensuring that they do not pull out. A squeezing pressure of 30 pounds is applied to the skull when the pins are properly positioned.⁵ An S-shaped hook is permanently attached to the top of the Gardner-Wells tongs. The rope and traction weights are attached to this hook. Permanently attached to the S-hook is a metal plate that is engraved with the instructions (**Figure 150-3**). **The instruction plate faces**

FIGURE 150-2. The calibration pin of the Gardner-Wells tongs.

FIGURE 150-3. Instructions for the use of the Gardner-Wells tongs. (Photo courtesy of Eric F. Reichman, PhD, MD.)

FIGURE 150-4. Application of the Gardner-Wells tongs to a human skull. (Photo courtesy of Eric F. Reichman, PhD, MD.)

upward and is readable when the Gardner-Wells tongs are properly applied (Figures 150-4 and 150-5).

PATIENT PREPARATION

Explain the procedure, its risks, and benefits to the patient and/or their representative. Obtain an informed consent to apply the Gardner-Wells tongs. Signed consent may be omitted in cases where the patient is immobilized or has an altered mental status. Document the reason for the lack of a signed consent in the medical record. Intravenous sedation may be required in certain cases and is at the discretion of the treating Emergency Physician.

Consider the use of some form of deep venous thrombosis prophylaxis since the application of Gardner-Wells tongs requires the patient to remain bedridden. The use of sequential compressive devices is simple, easily applied in the Emergency Department, and will not cause complications. Consult a Spine or Neurological Surgeon before prescribing intravenous, oral, or subcutaneous anticoagulants that could have grave bleeding complications in a cervical trauma patient.

Identify the anatomic landmarks required to place the Gardner-Wells tongs. The pins are introduced in the temporal region, two to three fingerbreadths (i.e., 3 to 4 cm) cephalad to the pinna of the

ear (Figure 150-5). Place them directly above the external auditory meatus for neutral distraction, 2 to 3 cm posterior to the external auditory meatus for flexion distraction, and 2 to 3 cm anterior to the external auditory meatus for extension distraction. A helpful landmark is the squamosal line where the temporalis muscle inserts into the skull. **Place the Gardner-Wells tongs below the squamosal line to allow adequate traction.** Another useful landmark is to observe for the widest biparietal diameter of the patient's skull. This usually corresponds to the landmark just inferior to the squamosal line.

The use of Gardner-Wells tongs does not require shaving the patient's hair at the proposed pin sites. Clipping the hair can improve patient comfort and postapplication care. Clean the skin and hair of any blood, dirt, and debris. Apply povidone iodine solution to the skin and hair at the proposed pin sites. Allow the povidone iodine to dry. Use sterile technique and infiltrate 1 mL of lidocaine with epinephrine into each of the two proposed pin sites. Infiltrate subcutaneously and down to the level of the periosteum of the skull.

TECHNIQUE

The Gardner-Wells tongs are fast and easy to apply by one person. An assistant standing at the patient's feet can confirm that tongs are placed symmetrically. Another assistant may be needed to maintain

FIGURE 150-5. Application of the Gardner-Wells tongs. **A.** It can be positioned and applied without shaving the patient's entire head. **B.** Schematic demonstrating the pin position into the skull.

FIGURE 150-6. The calibration pin indicator is at 1 mm when the pins are properly seated in the skull.

the patient's head position during the procedure. The patient should already be supine on the gurney. Stand above the patient's head. Assemble the Gardner-Wells tongs by inserting the pins into the threaded holes.

Place the pins of the Gardner-Wells tongs over the proposed pin insertion sites of the patient's head. **The instructions on the S-hook must be facing upward and readable. The Gardner-Wells tongs are upside down if the instructions are not facing upward.** Apply the Gardner-Wells tongs so the pins are symmetrically located on each side of the head. The assistant at the foot of the bed can ensure symmetry of pin placement. Screw in the pins equally and simultaneously on both sides of the tongs (**Figure 150-5B**). Note that the small spring-loaded indicator pin is observed on one side of the tongs when adequate tension is applied (**Figures 150-2 and 150-6**). Recommendations by the manufacturer suggest that the pins should be tightened simultaneously until there is a 1 mm protrusion of the indicator pin beyond the flat surface (**Figure 150-6**). Tighten the securing nuts to prevent the tongs from loosening (**Figure 150-2**).

The points of the pins will not pull out when properly applied. The depth of penetration of the pins is self-limited by a gradual lessening of the spring tension and an increase in the surface area of contact between the tips of the pins and the skull. The pressure exerted by each pin is exactly the same, regardless of whether one pin has been advanced farther than the other. The curve of the rigid rod allows the traction loop to find its proper position.

CONSIDERATIONS FOR PEDIATRIC PATIENTS

There are significant anatomic differences in children below the age of 8 years. The large occiput of children produces a cervical kyphosis. It is recommended to elevate the torso with soft padding to prevent excessive kyphosis and allow for a more anatomic alignment of the cervical spine when immobilized on a spine board or a stretcher.

ALTERNATIVE TECHNIQUES

There are halo tongs that can be used. They usually include four pins instead of two with the Gardner-Wells tongs. They can be attached to a pulley system with weights to reduce and stabilize the cervical spine. They can alternatively be attached to a halo vest for stability (**Figure 150-7**). This device is reserved for the consultant.

APPLICATION OF TRACTION WEIGHTS AND ASSESSMENT

Gently rock the Gardner-Wells tongs to assure that the pins are properly seated within the outer table of the skull (**Figure 150-8**). Place the patient in the reverse Trendelenburg position (**Figure 150-9**).

A

B

FIGURE 150-7. The halo tongs attached to a vest. **A.** Overview. **B.** Close-up of the tongs. (Photos courtesy of Eric F. Reichman, PhD, MD.)

Tie the provided rope to the S-shaped hook. Feed the other end of the rope through a pulley at the head of the bed and apply weights. Proper attention to the head position and the axis of distraction are important elements in achieving closed reduction. Initially apply a 10 pound weight.⁸ Obtain a lateral cervical spine radiograph 10 to

FIGURE 150-8. The Gardner-Wells tongs have been applied. The arms are grasped and gently twisted to confirm proper seating of the pins.

15 minutes after the application of the weight. Add 3 to 5 pound weights, one at a time, for each vertebral segment above the level of the injury. Obtain a lateral cervical spine radiograph 10 to 15 minutes after each 3 to 5 pound weight is added and reassess the neurologic exam. Continue to increase the traction weight in 3 to 5 pound increments. Continue to repeat lateral cervical spine radiographs and neurologic exams 10 to 15 minutes after each additional weight is added. **Stop adding weights when the radiographs demonstrate appropriate alignment of the cervical spine. Careful assessment and documentation of the patient's neurologic function are mandatory throughout the application of weights and skeletal traction to prevent overdistraction and iatrogenic injury.**

AFTERCARE

Clean the pin sites every shift with povidone iodine or hydrogen peroxide solution followed by iodine ointment. Obtain daily cervical spine radiographs to follow the spinal alignment and pin placement. Very slowly reduce the weight by 50% to maintain the alignment if spinal realignment is obtained with traction. Monitor the patient's airway status, anxiety level, and for the development of pressure ulcers given their immobilization. Confirm that sequential compression devices are applied to the legs and functional to

FIGURE 150-9. The patient is placed in reverse Trendelenburg and traction is applied.

prevent thromboembolic complications. Ensure proper patient padding as pressure ulcer development is common and preventable.

The points of the pins tend to penetrate the outer table of the skull due to the continuous pressure exerted by the springs on a very small area. **Readjust the pins in 24 hours, again setting the indicator pin so that it protrudes approximately 1 mm from the flat surface. Further adjustment of the Gardner-Wells tongs is not necessary and is not recommended as it can result in erosion of the pinpoint through the skull.**

Interfacility transport may become necessary to provide higher level of patient care after the application of Gardner-Wells tongs. Expert advice is to place the patient back into a ridged cervical collar, use side-by-side immobilizers, and tape the patient's head to a long spine board. Secure the weights attached to the pulley system to prevent their movement. **Take extreme caution when transferring the patient to prevent excessive distraction or loss of traction.**

COMPLICATIONS

Skull penetration from placing the pins too low in the temporal region where the skull is thinnest can lead to dural tears, epidural hematomas, and possibly intracranial injury.¹⁸⁻²⁰ Pins located in the temporal fossa pierce the temporalis muscle and can cause painful mastication. Overdistraction can lead to iatrogenic injury. This is best prevented by the initial use of a minimal amount of weight necessary to distract or reduce the cervical spine injury. Pin site infections are prevented by close attention to surgical technique and daily hygiene with the addition of topical antibiotic ointment. Other complications reported include intracranial aneurysms, cerebrospinal fluid leaks, and osteomyelitis of the skull.

SUMMARY

The application of skeletal traction in the form of Gardner-Wells tongs is a safe, simple, and quick procedure when there is evidence of clinical or radiologic cervical spine instability and no immediate plans for definitive therapy. It requires only local anesthesia and anti-septic preparation of the skin. Careful attention to the application technique using the suggested anatomic landmarks will reduce the chances of complications. Monitoring realignment and/or reduction procedures with frequent cervical spine radiographs and neurologic exams after each traction weight applied is essential. Gardner-Wells tongs are not recommended as a long-term immobilization technique. Definitive management of cervical spine instability requires surgical stabilization and/or halo bracing.

Reflex Eye Movements (Caloric Testing and Doll's Eyes)

Atilla B. Üner

INTRODUCTION

A central nervous system-induced coma is either the result of bilateral diffuse impairment of the hemispheres or impairment of the paramedian reticular formation in the high pons of the brainstem. Examination of the pupils and reflex horizontal eye movements (i.e., vestibulo-ocular reflex and oculoccephalic reflex) in the Emergency Department will aid in determining the location of the lesion responsible for the comatose state to either the brainstem, the hemispheres, or both.^{1,2} When more information is available, a neurologic exam including reflex eye movements can aid in determining the prognosis of patients in a nontraumatic coma including patients successfully resuscitated from cardiac arrest.³ **This testing is considered to be part of a thorough and complete neurologic examination in the comatose patient.**

ANATOMY AND PATHOPHYSIOLOGY

EXAMINATION OF THE PUPILS

It is imperative to first assess the pupillary reflex to light and the presence of spontaneous eye movements in the comatose supine patient. The pupillary light reflex involves the pretectal nuclei in the upper midbrain of the brainstem.⁴ Damage to areas of the brainstem can result in characteristic abnormalities of the pupils.¹ Pontine lesions can produce pinpoint pupils with preserved reaction to light upon close examination. Midbrain tegmental lesions can result in midrange pupils that may be irregular, unequal, and unreactive to

light. Midbrain pretectum lesions may cause midrange fixed pupils that do respond to accommodation.

Impaired brainstem function may be seen in patients who are in a toxic or metabolic coma. This can present with impaired eye movements or a complete ophthalmoplegia. Pupillary function is preserved in these cases. **Preserved pupillary function in a comatose patient suggests decreased brainstem function likely caused by a toxic or metabolic disorder and not structural damage to the brainstem.**¹

Spontaneous roving eye movements in the comatose patient are typically slow and horizontal, indicating bilateral hemispheric disease with a relatively intact brainstem (e.g., the pons and the midbrain).^{1,2} Ocular dipping describes the slow downward movement of the eyes with rapid return to a neutral position with preserved spontaneous roving horizontal eye movements and suggests global hypoxic encephalopathy.¹ Ocular bobbing describes an intermittent rapid downward movement of the eyes with delayed return to a neutral position in the absence of horizontal eye movements and suggests severe damage to the pons (e.g., the "locked-in syndrome").¹

Spontaneous full roving eye movements or impaired eye movements with preserved pupillary reaction to light permit adequate localization of the cause of coma. Further testing of reflex eye movements is only indicated if spontaneous lateral eye movements are limited or absent.^{1,2}

OCULOCEPHALIC REFLEX (DOLL'S EYES)

The brainstem is comprised of the medulla, the pons, and the midbrain. It contains all three nuclei involved in the oculoccephalic reflex. **Hence an intact oculoccephalic reflex response suggests intact brainstem function.**² The lateral semicircular canals, the vestibulocochlear nerve, the abducens nerve, the oculomotor nerve, and the medial and lateral ocular rectus muscles must also be intact for a physiologic response to occur. **The optic nerve is not involved and vision or light perception is not required for this reflex to function.**

A simplified model of the physiologic oculoccephalic reflex is described in this paragraph. Neural stimulation of the lateral semicircular canal is mediated by the inertia of the endolymph fluid resulting in a deflection of the cupula that is directly proportional to instantaneous head velocity.⁵ Fairly rapid movements are necessary to elicit a response. Neural excitation from the lateral semicircular canal travels via the ipsilateral vestibulocochlear nerve to the ipsilateral medial vestibular nucleus in the medulla. It continues from there to the contralateral abducens nucleus in the pons and results in abduction of the contralateral eye via the abducens nerve and the lateral rectus muscle. The contralateral medial longitudinal fasciculus then excites the ipsilateral oculomotor nucleus in the ipsilateral midbrain, resulting in ipsilateral eye adduction via the oculomotor nerve and the medial rectus muscle (Figure 151-1).¹

Turning the head to one side will cause an increase in the resting neuronal discharge rate of the lateral semicircular canal on that side. **Turning the head to the right will result in abduction of the left eye and adduction of the right eye in a comatose patient whose brainstem function is intact (Figures 151-1A and 151-1B). The eyes then spontaneously return to the midline (Figure 151-1C). Turning the head to the left will result in abduction of the right eye and adduction of the left eye in a comatose patient whose brainstem function is intact (Figure 151-1D). The eyes then spontaneously return to the midline (Figure 151-1E). The result is conjugate (i.e., parallel) eye movement contralateral to the direction of head deviation.** It will appear as though the patient is compensating for the passive head motion by moving both eyes to the other side and maintaining visual fixation of a stationary target

FIGURE 151-1. The oculocephalic or doll's eyes reflex in a patient with an intact brainstem. **A.** The head is facing upright and grasped. **B.** The head is rotated 90° to the right and the eyes deviate to the left (i.e., the opposite side). **C.** The eyes spontaneously return to the midline. **D.** The head is rotated 180° to the left and the eyes deviate to the right (i.e., the opposite side). **E.** The eyes spontaneously return to the midline.

when the head is turned. This indicates an intact brainstem function and is termed a positive oculocephalic reflex (i.e., positive doll's eyes). A negative oculocephalic reflex ensues if the patient's eyes remain fixed in the orbits in a neutral position and do not move in response to passive turning of the head, implying impaired brainstem function. A partial response may be caused by impaired brainstem function, oculomotor nerve palsy, or abducens nerve palsy.²

A vertical oculocephalic response can similarly be tested by moving the head up and down.⁶ This should result in compensatory vertical eye movements. This test will only be useful if the horizontal oculocephalic reflex is negative. A positive (i.e., intact) vertical oculocephalic reflex with a negative horizontal oculocephalic reflex suggests a pontine lesion. However, the vertical oculocephalic reflex is often negative in normal elderly patients and is only helpful if positive.¹

VESTIBULO-OCULAR REFLEX

Ice and warm water caloric testing of the vestibulo-ocular reflex involves the same structures as the oculocephalic reflex (Figure 151-2).

This test needs only to be performed when the oculocephalic reflex is negative or cannot be performed.² Instilling ice water into the external auditory canal generates a temperature gradient that causes movement of the endolymph of the lateral semicircular canal.^{7,8} This results in an ampullifugal deflection of the cupula in the supine patient, leading to a decrease in the lateral semicircular canal resting neuron discharge rate on the ipsilateral side and an active increase of the resting neuron discharge rate of the medial vestibular nucleus on the contralateral side. This leads to an activation of the contralateral medial vestibular nucleus of the medulla resulting in conjugate eye deviation to the ipsilateral side (i.e., toward the ice water irrigated side) if all involved brainstem structures are intact.^{1,2}

Irrigation of the external auditory canal with warm water will cause an increase in the resting neuron discharge rate of the ipsilateral lateral semicircular canal and conjugate eye deviation to the contralateral side (i.e., away from the warm water irrigated side). The results are reverse if the patient is prone.^{1,2,9}

Density changes caused by temperature changes of the endolymph demonstrate the greatest effect when the lateral semicircular

FIGURE 151-2. The vestibulo-ocular reflexes associated with unilateral cold water irrigation, bilateral cold water irrigation, and bilateral warm water irrigation.

canals are in the vertical planes for maximum gravity effect. This is achieved by elevation of the supine patient's upper body to 30° above the horizontal.⁷⁻⁹ The observable oculomotor response is terminated after about 100 seconds by neural adaptation, although the residual thermal stimulation of the lateral semicircular canal can last up to 10 minutes.⁷

Unilateral vestibulo-ocular testing in an awake patient with ice water results in slow eye movements (i.e., slow phase nystagmus) ipsilateral to (i.e., toward) the irrigated side and rapid eye movements (i.e., fast phase nystagmus) contralateral to (i.e., away from) the irrigated side (**Figure 151-2**). Warm water testing in an awake patient results in slow eye movements (i.e., slow phase nystagmus) contralateral to (i.e., away from) the irrigated side and rapid eye movements (i.e., fast phase nystagmus) ipsilateral to (i.e., toward) the irrigated side. This quick phase, if present, indicates alertness of the pontine or midbrain reticular formation.¹ **The direction of nystagmus is named after the direction of the quick phase, giving rise to confusion.**

Bilateral vestibulo-ocular testing in an awake patient can be used to test vertical eye movements (**Figure 151-2**). Bilateral cold water irrigation results in slow eye movements (i.e., slow phase nystagmus) downward and rapid eye movements (i.e., fast phase nystagmus) upward. Bilateral warm water irrigation results in slow eye movements (i.e., slow phase nystagmus) upward and rapid eye movements (i.e., fast phase nystagmus) downward.

The presence of nystagmus indicates a noncomatose state. Typical examples of noncomatose states include catatonia, conversion

reactions, malingering, psychiatric illness, or schizophrenia. Hypoactive responses can be due to neurologic disorders, vestibular disorders, or medications that depress labyrinth function.⁸ Hyperactive responses in unresponsive patients can be due to mastoid disease or a perforated tympanic membrane.

Rapid phase nystagmus is absent in the patient with an acute coma. The quick phase may return with persistent vegetative states. It is important to note the slow and full eye deviation in response to caloric stimulation when assessing the comatose patient and not nystagmus.^{1,2}

INDICATIONS

Reflex eye movement testing is indicated when information is needed regarding the brainstem function of a comatose patient. Oculocephalic reflex (i.e., doll's eyes) testing is indicated in any comatose patient if both spontaneous roving horizontal eye movements and pupillary reactions to light are limited or absent. Vestibulo-ocular reflex testing is indicated in any comatose patient if the oculocephalic reflex assessment is abnormal or cannot be performed.^{1,3}

CONTRAINDICATIONS

Any suspicion of an occult cervical spine injury or basilar skull fracture is an absolute contraindication to oculocephalic reflex (i.e., doll's eyes) testing. It cannot be performed if the patient's cervical

spine is immobilized. A history of rheumatoid arthritis increases the risk of atlantoaxial subluxation with resulting spinal cord compression. Osteoporosis and cervical spine ankylosis increase the risk of injury to the cervical spine with manipulation. Other than an occult cervical spine injury or basilar skull fracture, these are relative contraindications to oculoccephalic reflex testing.

Contraindications to vestibulo-ocular reflex testing include perforation of the tympanic membrane, the presence of tympanostomy tubes, any suspicion of cerebrospinal fluid otorrhea, and basilar skull fractures. There is a significant risk of introducing bacteria into the central nervous system through a tear in the dura mater. Reflex testing with cold air by a subspecialty service may be requested for patients with perforated tympanic membranes.⁸

EQUIPMENT

- Otoscope
- Warm water at 44°C
- Ice water
- 16 to 18 gauge angiocatheter
- 60 mL syringe
- Emesis basin
- Towels or chux

PATIENT PREPARATION

Explain the procedure, its utility, and potential outcomes to the patient's representatives. Place the patient supine for testing. **The cervical spine must be cleared radiographically and clinically to rule out any fractures, dislocations, or ligamentous instability before oculoccephalic reflex (i.e., doll's eyes) testing.**

The external auditory canals and tympanic membranes must be visualized by otoscopy before performing vestibulo-ocular reflex testing. The absence of blood, cerebrospinal fluid, tympanostomy tubes, and tympanic membrane perforation must be ascertained before performing this test. **Remove any cerumen from the external auditory canal so that the irrigation fluid can reach the tympanic membrane.** Place towels and an emesis basin under the ear to be irrigated to catch the draining fluid.

TECHNIQUES

OCULOCEPHALIC REFLEX TESTING

Stand above the head of the bed and grasp the patient's head with both hands (**Figure 151-1A**). Use the thumbs of both hands to open the patient's eyelids. Rapidly move the patient's head to one side while simultaneously observing for the presence or absence of horizontal eye movements (**Figures 151-1B and 151-1C**). Observe the eyes for several seconds. Repeat the test by rotating the patient's head toward the other side (**Figures 151-1D and 151-1E**). Document the presence or absence of horizontal eye movements.

VESTIBULO-OCULAR REFLEX TESTING

Elevate the head of the bed to 30°. Draw ice water into a 60 mL syringe. Remove the plastic angiocatheter from the needle. Discard the needle. Place the catheter on the syringe. Place the catheter into the external auditory canal. Irrigate the external auditory canal over 30 to 40 seconds with the ice water. Simultaneously observe the patient's eyes for the presence, or absence, and

direction of horizontal eye movements.^{1,8} The water should freely enter and exit the external auditory canal.⁹ The stimulus is dependent upon the water temperature and not water pressure. Therefore, slow irrigation will suffice. Reflex horizontal eye movements may be delayed for up to 1 minute after irrigation of the external auditory canal.¹ It may be easier for the physician to observe the patient's eye movements while an assistant irrigates the external auditory canals.

At least 5 to 10 minutes should elapse before testing the contralateral side.¹ The same external auditory canal can also be irrigated with warm water at 44°C (111.2°F) if, for any reason, the contralateral side cannot be tested. Warm water testing may be performed if there is no response to cold testing. Some physicians also perform simultaneous bilateral external auditory canal irrigation and observe for vertical eye movements. This requires the simultaneous irrigation of both external auditory canals with equal volumes of water.

ASSESSMENT

OCULOCEPHALIC REFLEX TESTING

Head movement to the right should result in conjugate eye movement to the left and return to midline, whereas head movement to the left should result in conjugate eye movement to the right and return to midline (**Figure 151-1**).¹⁰ **This is a positive oculoccephalic reflex and indicates a functionally intact brainstem in the comatose patient. Incomplete or absent horizontal eye movements in response to head movement (i.e., the eyes remain in the midline) is a negative oculoccephalic reflex. This indicates impairment of the brainstem and vestibulo-ocular reflex testing should be performed if not contraindicated.**

VESTIBULO-OCULAR REFLEX TESTING

Full horizontal eye movements indicate that the etiology of the coma is located in the cerebral hemispheres and not in the brainstem. This is true whether the eye movements are noted spontaneously, upon oculoccephalic reflex testing, or upon vestibulo-ocular reflex testing. Unilateral ice water irrigation of the external auditory canal resulting in ipsilateral conjugated full eye deviation (i.e., toward the irrigated ear) followed slowly by a returning to midline is a positive response. Unilateral warm water irrigation of the external auditory canal resulting in contralateral full eye deviation (i.e., away from the irrigated ear) followed slowly by a return to midline is a positive response. **A positive response indicates intact brainstem function. Impaired or absent reflex horizontal eye movements indicates impaired brainstem function at or below the level of the oculomotor nucleus.** This may or may not be the sole cause of the patient's coma.^{1,2}

Full vertical eye movements indicate that the etiology of the patient's coma is located in the cerebral hemispheres and not in the brainstem. Bilateral ice water irrigation of the external auditory canals resulting in downward movement of the pupils followed slowly by a return to midline is a positive response. Bilateral warm water irrigation of the external auditory canals resulting in upward movement of the pupils followed slowly by a return to midline is a positive response. **A positive response indicates an intact brainstem function. Impaired or absent reflex vertical eye movements indicate impaired brainstem function at or below the level of the oculomotor nucleus.**

Absent bilateral vestibulo-ocular reflexes in a comatose patient may be due to a variety of reasons. Inadequate irrigation can be due

to cerumen impaction, low irrigation volumes, or poor technique. These causes are obvious and easily corrected. The patient may have other causes for the coma including toxin-induced and metabolic. The patient may also have a preexisting dysfunction of their vestibular apparatus.

AFTERCARE

Dry the patient off to prevent skin maceration from moisture if vestibulo-ocular reflex testing was performed. Examine the tympanic membranes and external auditory canals to assess for any injury related to the testing.

COMPLICATIONS

No significant complications are to be expected if patients with contraindications are excluded. Injury to the tympanic membrane and external auditory canal can occur from the angiocatheter or forceful irrigation. Never use a sharp or metal object to irrigate the external auditory canals. Other potential complications from vestibulo-ocular reflex testing include meningitis, otitis media, and vomiting.

SUMMARY

Central nervous system-induced coma can occur only in the presence of bilateral or diffuse hemispheric lesions, brainstem lesions, or a combination of both. Spontaneous roving eye movements are seen in bilateral hemispheric disease with a relatively intact brainstem. Perform oculocephalic reflex testing if spontaneous roving eye movements in the comatose patient are impaired or absent. The brainstem function is intact if passive turning of the patient's head results in conjugate contralateral eye deviation.

Vestibulo-ocular reflex testing needs only to be performed when oculocephalic reflex testing is abnormal or cannot be performed. Irrigation of the ear canal with ice water will result in eye deviation toward the irrigated ear in the comatose patient with intact brainstem function. Intact full reflex horizontal eye movement indicates that the lesion or lesions causing the coma lie in the cerebral hemispheres and not in the infratentorial brainstem. Incomplete or absent horizontal eye movements suggest a lesion in the brainstem, which may or may not be the sole cause of coma.

Myasthenia Gravis Testing

Eric F. Reichman

INTRODUCTION

Myasthenia gravis is an autoimmune disorder that occurs when polyclonal antibodies bind to a significant number of postsynaptic acetylcholine receptors at the neuromuscular junction leading to inadequate neuromuscular transmission.¹⁻⁴ It most commonly affects 10 to 30 year old females and 70 to 90 year old males. Multiple tests are available to diagnose myasthenia gravis.^{3,5-12} These include the use of muscle biopsies, curare, edrophonium chloride (Tensilon), electromyography, ice packs, neostigmine, nerve stimulation, and serologic testing. The edrophonium test is the most commonly used diagnostic test for myasthenia gravis.¹³⁻¹⁶ Many of these techniques are seldom used and not feasible to perform in the Emergency Department. For these reasons, only the edrophonium test and the ice pack test will be described in this chapter.

ANATOMY AND PATHOPHYSIOLOGY

Acetylcholine is a neurotransmitter of the neuromuscular junction that is released by the presynaptic nerve terminals when stimulated.^{5,17} An electrical potential is produced at the myoneural end plate when sufficient numbers of the postsynaptic receptors at the neuromuscular junction are bound by the released acetylcholine. This electric potential then propagates and ultimately leads to muscle contraction. Simultaneously, acetylcholinesterase rapidly terminates the neurotransmission by metabolizing the acetylcholine in the synaptic cleft of the neuromuscular junction.

Myasthenia gravis is an autoimmune disorder that occurs when polyclonal antibodies bind to postsynaptic acetylcholine receptors at the neuromuscular junction.^{2-5,17} This leads to inactivation of the receptors and inadequate neuromuscular transmission. Myasthenia gravis is characterized clinically by muscle weakness that develops after repetitive muscle contraction.

Patients are divided into two clinical groups. The first are patients who present with ocular complaints.¹⁰ Patients most commonly present with some degree of ocular muscle involvement. Diplopia is the most common patient complaint. Ptosis is the most visible sign noted on the physical examination. Diplopia with disconjugate gaze can be elicited by having the patient maintain a vertical gaze for approximately 3 minutes. Ptosis can also be made to worsen by having the patient maintain an upward gaze for the same duration of time. These patients may or may not have associated weakness of the pharyngeal and facial muscles that present with the complaints of dysarthria and dysphagia. These symptoms can often be elicited by having the patient count backward from 100.

The second group are patients with proximal muscle weakness. Weakness of the limbs usually involves the proximal muscles and may be asymmetric. Weakness of the muscles can be elicited by having the patient perform repetitive exercises involving the muscle groups in question. **Involvement of respiratory and pharyngeal muscles should be taken very seriously as it may lead to respiratory failure or aspiration.**^{2,3,18-21}

Edrophonium chloride is a short-acting acetylcholinesterase inhibitor (anticholinesterase) used in the diagnosis of myasthenia gravis.^{3,17} Its onset of action is rapid (within 1 to 2 minutes) and the duration of action is brief (2 to 5 minutes). These characteristics make it ideal to use in the Emergency Department. Edrophonium

given intravenously to patients with myasthenia gravis briefly inhibits the actions of the acetylcholinesterase, thus prolonging the interaction between the acetylcholine and the postsynaptic receptors. This results in a temporary but noticeable improvement in muscle contraction.^{1,20} Edrophonium can rapidly, and temporarily, reverse the signs and symptoms of myasthenia gravis.

INDICATIONS

Testing is indicated when the patient's condition is suggestive of myasthenia gravis.^{5,6} Edrophonium chloride can be used for patients presenting with diplopia, facial muscle weakness, appendicular muscle weakness, or ptosis suggestive of myasthenia gravis. The ice pack test is reserved to evaluate patients presenting with ptosis.²²⁻²⁴

CONTRAINDICATIONS

There is the possibility of worsening the patient's symptoms, causing respiratory distress or arrest, and cardiac dysrhythmias. Do not administer edrophonium if resuscitative equipment, Advanced Cardiac Life Support medications, and additional support personnel are not immediately available. Edrophonium should not be administered if the Physician is not properly trained in airway management and rescue techniques. Use caution when administering edrophonium if the patient's medications can cause atrioventricular node blocking or slowing of transmission (e.g., beta-blockers, calcium channel blockers, and digoxin). These can make the edrophonium associated dysrhythmias more pronounced.

Edrophonium testing is relatively contraindicated in patients with known myasthenia gravis who are taking oral pyridostigmine (Mestinon) and present with increasing weakness. The weakness may be due to insufficient drug treatment (myasthenic crisis) or too much drug treatment (cholinergic crisis).³ The terminology regarding these types of crises is controversial and beyond the scope of this chapter.^{25,26} The patient will improve with edrophonium testing if the etiology of the weakness is a myasthenic crisis. The symptoms will worsen with edrophonium testing if the etiology of the weakness is a cholinergic crisis. Consult a Neurologist, for these reasons, prior to performing an edrophonium test on a patient with known myasthenia gravis who is already taking oral anticholinergic medications.

A patient with known myasthenia gravis complaining of respiratory distress should be assessed and managed similar to any other patient with respiratory compromise. An edrophonium test is contraindicated if it is being used to improve a patient's respiratory distress. A cholinergic crisis treated with edrophonium can further compromise the patient's respiratory status, possibly leading to a respiratory arrest.

The use of edrophonium is contraindicated in pregnancy. It may induce the patient into preterm labor. A neostigmine test is safer if testing is required. Testing should be performed only after consultation with an Obstetrician and a Neurologist.

Edrophonium testing is relatively contraindicated in patients with asthma, bronchospastic disease, cardiac dysrhythmias, or if a group of muscles that are weak are not easily observable. Edrophonium testing should be deferred in favor of neurologic consultation and consideration of other testing methods.

EQUIPMENT

- 10 mg edrophonium chloride (Tensilon)
- Tuberculin syringe
- 10 mL syringe containing 9 mL of sterile normal saline

- Intravenous access with normal saline solution attached to the IV catheter
- Cardiac monitor
- Pulse oximeter
- Noninvasive blood pressure monitor
- Supplemental nasal oxygen
- Resuscitative equipment and medications
- Digital camera or Polaroid camera with instant film
- Ice pack, ice cubes, or instant cold packs

PATIENT PREPARATION

Explain the risks, benefits, and potential complications to the patient and/or their representative. Obtain a signed consent for the procedure. Place the patient sitting upright or supine in a bed. Obtain intravenous access. Apply supplemental oxygen, pulse oximetry, cardiac monitoring, and noninvasive blood pressure monitoring. **Resuscitative equipment and medication must be immediately available in the room if required.**

Identify a group of muscles that can easily be observed and monitored for improvement of function. If possible, the muscle group to be tested should be fatigued. For example, have the patient look upward for 3 minutes to accentuate ptosis. Muscle groups of the extremities can be exercised for several minutes until the patient experiences fatigue. Take a picture, if a camera is available, of the muscle group to be observed after it has been fatigued. This is the "before" photograph.

Prepare the edrophonium chloride. **It is essential that the edrophonium concentration be accurate regardless of who (i.e., Emergency Physician, Nurse, or Pharmacist) prepares the solution.** It is supplied in a concentration of 10 mg/mL. Using sterile technique, transfer 10 mg (1 mL of 10 mg/mL) of edrophonium into a syringe containing 9 mL of sterile normal saline. The resulting solution will contain 1 mg of edrophonium chloride per mL of fluid. **Verify the concentration of the edrophonium solution prior to use, especially if it was made by someone else.**

TECHNIQUE

Administer the edrophonium soon after the weakened muscle is identified, carefully noted, and fatigued. Ideally, one person should administer the medication while another person observes the patient for the effects of the edrophonium chloride. **It may be administered in increasing doses up to a total of 10 mg.** Inject 1 mg (1 mL) of edrophonium chloride intravenously followed by a saline flush. Physical improvement in the observed muscle group should be seen within 30 seconds to 2 minutes if the edrophonium is effective. Muscle improvements will revert to their original state after 2 to 3 minutes. **The test is concluded if there is a positive response to the edrophonium in the observed muscle group.** Inject 3 mg (3 mL) of edrophonium chloride intravenously followed by a saline flush if there is no improvement after the first dose. **The test is concluded if improvement is seen in the muscle group.** Inject the remaining 6 mg (6 mL) of the edrophonium chloride intravenously followed by a saline flush if there is no response within 2 to 3 minutes after the second dose. **The test is considered negative and concluded if there is no response to the third dose of edrophonium (total of 10 mg).** A negative test argues against myasthenia gravis but does not completely exclude the diagnosis.^{19,21}

Some Neurologists prefer to give the entire 10 mg (10 mL) dose of edrophonium chloride as a single intravenous bolus and observe the muscle group for improvement. **This has the potential to cause significant bradycardia and is not recommended.**

The total dose of edrophonium to administer to children is 0.15 mg/kg, not to exceed 10 mg of edrophonium.⁶ An initial dose of 1 mg is appropriate for children. Administer subsequent doses of 1 to 2 mg to a maximum of 0.15 mg/kg or 10 mg of edrophonium.

ALTERNATIVE TECHNIQUE

ICE PACK TEST FOR OCULAR MYASTHENIA GRAVIS

The ice pack test can be used to diagnose patients with ocular signs of myasthenia gravis.^{22-24,27} This test is reserved for the patient presenting with ptosis and/or diplopia suggestive of myasthenia gravis. The basis of this test is the finding that patients with myasthenia gravis have symptoms that worsen in warm weather and that improve in cold weather. Based on this clinical observation, studies have shown that placement of a bag of ice directly over the eyes of myasthenia patients with ptosis actually relieved the symptoms and signs of ocular myasthenia gravis.^{22,23} This test is quick, simple, inexpensive, and easy to perform in the Emergency Department. It has none of the potential complications associated with the intravenous administration of edrophonium chloride. There are no contraindications to performing this test.

Place a bag of ice directly over the eye with ptosis and/or diplopia for 2 minutes or until the patient is no longer able to tolerate the cold. An alternative to an ice pack is ice cubes placed in a glove or instant cold packs that are activated by compression. Remove the ice pack from the eye and observe the patient for any improvement in the ptosis or diplopia. **A clear improvement of the ptosis indicates a positive test.** This test may be limited by the patient's intolerance to the cold of the ice pack.

ASSESSMENT

These tests can be positive and confirm the diagnosis of myasthenia gravis. **Objective findings of improved muscle function must be observed to identify the test as positive.** It is very common to observe fasciculations of the facial muscles or tongue after the intravenous administration of edrophonium chloride. **Muscle fasciculations are not considered a positive test.** The patient having the subjective feeling of "feeling better" without objective evidence of improved muscle function is also not considered a positive test. Document improvement by taking a photograph. This is the "after" photograph. Place both the "before" and "after" photographs in the patient's medical record.

AFTERCARE

Many medications used in the Emergency Department and prescribed to a patient at discharge can worsen myasthenia gravis and cause weakness (**Table 152-1**). Look up all current medications as they may be the cause of worsening symptoms in a known

TABLE 152-1 Some of the Medications That Worsen Myasthenia Gravis²⁸⁻³⁰

Aminoglycosides	General anesthetics	Penicillins
Antidysrhythmics	Interferon	Phenothiazines
Antiepileptics	Iodinated contrast media	Procainamide
Beta-blockers	Local anesthetics	Quinidine
Calcium channel blockers	Magnesium	Quinine
Chloroquine	Narcotic analgesics	Statins
Clindamycin	Neuromuscular blockers	Steroids
Estrogens	Nitrofurantoin	Sulfonamides
Fluoroquinolones	Ophthalmic beta-blockers	Telithromycin

myasthenia gravis patient. Look up all medications before administering them in the Emergency Department or writing a prescription.

The patient may be safely discharged if they are ambulatory and without respiratory distress. All patients with suspected or proven myasthenia gravis should be referred to their Primary Care Physician and a Neurologist for further evaluation and management.

COMPLICATIONS

Muscarinic side effects can be seen due to the prolonged cholinergic stimulation in patients hypersensitive to edrophonium chloride. These effects include increased salivation, increased lacrimation, and miosis. Some patients may experience bradycardia, junctional rhythms, and ventricular dysrhythmias due to the increased vagal effects of the prolonged acetylcholine stimulation of the heart.¹⁷ Older patients may experience a resultant postural syncope. **These effects are usually transient and self-limited. Intravenous atropine in low doses (0.5 mg) is effective to counteract any of the above symptomatology.**

There are no complications associated with the proper use of the ice pack test. Leaving the ice pack on the eyelids too long can result in a frostbite injury.

SUMMARY

Myasthenia gravis is an autoimmune disease that results in muscle weakness. The edrophonium test allows for a rapid, simple, and safe way to diagnose myasthenia gravis in the Emergency Department. The ice pack test for ocular myasthenia gravis offers a simple alternative to diagnose myasthenia gravis. Obtain prompt Neurologic consultation for all patients presenting with signs and symptoms suggestive of myasthenia gravis.

Anesthesia and Analgesia

153

Local Anesthesia

Mark Supino and Daniel Yousef

INTRODUCTION

Modern medicine can trace the use of local anesthetics back to the year 1884 when the Austrian Physician Karl Koller first used topical cocaine to assist with an ophthalmologic operation.¹ The premier Surgeon William Halstead first used injected cocaine to generate the intentional blockade of nerve transmission the following year.² Halsted's experiments with cocaine soon led to a concurrent dependency.³ The emerging illicit market for this compound soon prompted the search for a less toxic agent.³ Procaine, more commonly known by its trade name Novocain, was the first synthetic local anesthetic. It is a benzoic acid ester derivative developed by the German chemist Alfred Einhorn in 1904. Procaine had fewer drawbacks than its cocaine predecessor but was far from the ideal agent. Lidocaine was the first amide local anesthetic agent and was initially produced in 1945. The market for more effective agents continued to blossom. No less than 20 additional agents were developed for use as local anesthetics, each possessing unique pharmacokinetic properties to tailor its utility to specific clinical applications. They are all synthetic derivatives of cocaine.

The clinical utilization of these agents has become widespread throughout all medical specialties parallel to the proliferation in pharmacologic development. The daily practice of Emergency Medicine presents multiple scenarios that necessitate their use. **The Emergency Physician must maintain a familiarity with the local anesthetic agents available and their individual characteristics, have an expertise in their delivery, be well-informed of the potential side effects, and know how to avoid and treat adverse reactions to ensure the safest and most optimal pain relief.**

PHARMACOLOGY AND PATHOPHYSIOLOGY

Neuronal function and signal conduction are dependent upon a negative resting intracellular electrical potential (approximately -70 mV) as compared to the surrounding extracellular environment at a cellular level. This polarity results from the abundance of sodium (Na^+) cations found within the extracellular space. Membrane-based sodium-potassium (Na^+/K^+) pumps establish this sodium gradient. Adjacent voltage-gated sodium channels maintain the gradient by inhibiting the concentration of mediated and electrically driven sodium influx that would invariably result. A small intracellular sodium influx ensues upon the stimulation of an idle neuron. This sodium influx results in a slight depolarization of the resting membrane potential. The voltage-gated sodium channels reflexively open when a critical threshold of sodium influx is met. This results in a massive sodium ion influx and widespread membrane depolarization.⁴⁻⁶ Impulse transmission proceeds as this membrane depolarization is propagated down the entire length of the nerve fiber.⁷

Local anesthetic agents function by reversibly binding to membrane-based sodium channels and inhibiting the initial sodium

influx that results upon the stimulation of an idle neuron.⁴⁻⁹ If a significant number of these channels are blocked, the critical threshold of sodium influx required for the voltage-gated sodium channel opening cannot be met, widespread membrane depolarization cannot occur, and nerve impulses will not be transmitted. Careful examination of neuronal cells reveals that the binding sites for local anesthetic agents are located on the internal surfaces of their cellular membranes. The local anesthetic agent must first diffuse across the bilipid cellular membrane as an uncharged lipophilic compound. The local anesthetic agent is converted intracellularly to its active cationic state which terminates signal transduction and produces tissue anesthesia.¹⁰

All local anesthetic agents generally share the same molecular framework. They contain a lipophilic aromatic group linked to an ionizable group, usually a tertiary amine, via an intermediate linkage.^{4,7} This intermediate linkage is either an amino-amide or an amino-ester bond. This property is used to classify the local anesthetics as either "amides" or "esters." Further variations on this generalized structure generate the altered pharmacokinetics that impart the unique qualities to the individual local anesthetic agents.⁷

The potency of a given local anesthetic agent is directly proportional to its lipid solubility.^{9,11} More lipophilic agents tend to be more potent. The more soluble agent will readily diffuse across the cellular membrane despite a lower concentration of the extraneuronal anesthetic. A lower quantity of local anesthetic is needed to elicit the same endpoint response.¹² Variable potencies are rarely of significance to the Emergency Physician. The available preparations utilize concentrations of the local anesthetic specifically formulated to correct for this variation.

The primary determinant of a local anesthetic's onset of action is its pKa.¹³ The pKa is the pH at which a given drug exists in equal proportions as ionized and unionized molecules. The unionized molecules more readily cross the nerve cell membrane. A portion of the molecule becomes charged once inside the neuron. The ionized portion binds most completely to receptor proteins within the sodium channels.^{4,11} Commercially available local anesthetic agents are weak bases with pKas of 7.6 to 8.9.⁴ Agents with a lower pKa at physiologic pH (7.4) will have relatively more uncharged molecules free to cross the nerve cell membrane (i.e., faster onset) than agents with a higher pKa.^{6,11} Low tissue pH results in so little local anesthetic in the uncharged form that the agent is ineffective.⁶ This phenomenon explains why local anesthetics function poorly in acidic environments (e.g., abscess cavities) as a greater percentage of the agent is secondarily converted to its ionized state within the extracellular environment. It also explains why the addition of a buffering agent such as sodium bicarbonate increases the pH of the injected local anesthetic solution, increasing the ratio of nonionized local anesthetic agent present, and enhancing the rapidity of anesthesia onset. Increasing the total quantity of local anesthetic injected, whether by manipulating its concentration or increasing the overall volume, will hasten the onset of activity by augmenting the diffusion gradient and more aggressively driving the local anesthetic agent intracellularly.^{7,8} Local anesthetic agents with a higher intrinsic pKa generate more effective sodium channel blockade intracellularly via their tendency to persist in an ionized and functionally active

state.^{8,10} The rate at which a local anesthetic agent diffuses through surrounding nonneuronal tissues also appears to be an important variable.^{5,8}

A local anesthetic agent's duration of activity is typically proportional to the overall degree of protein binding.^{6-8,11} Those that possess a higher affinity for the target receptor are less likely to be dislodged and exhibit a longer duration of action.^{7,11} **All the available local anesthetic agents produce a degree of localized vasodilation.** This serves to increase regional blood flow, promote systemic absorption of extracellular fluid, and decrease the total duration of activity.^{5,7,11} Counteracting this phenomenon by compounding a vasoconstrictor such as epinephrine with the local anesthetic agent represents another practical way to increase the duration of action.^{4,14}

The two classes of local anesthetic agents undergo metabolism via different mechanisms.^{5,7,15-17} Esters are metabolized rapidly by plasma pseudocholinesterase to the major metabolite para-aminobenzoic acid (PABA).^{5,7,15} PABA is allergenic and likely responsible for the infrequent allergic reactions to ester agents.^{5,7,16} **Patients with atypical pseudocholinesterase activity are at increased risk for systemic toxicity from ester anesthetic agents.**^{16,17} Amide anesthetic agents are metabolized more slowly by the liver to a variety of metabolites that are unrelated to PABA. **Patients with impaired liver function are at increased risk for systemic toxicity from amide anesthetic agents.**^{16,17}

INDICATIONS

Local anesthetic agents are used in the Emergency Department for local infiltration, regional nerve blockade (Chapter 156), peripheral nerve blockade, and topical application (Chapter 154). General principles concerning their use and local infiltration will be discussed in this chapter. A complete review of specific techniques and procedures is available elsewhere in this text.

Localized injected anesthesia, or infiltrative anesthesia, represents the most widespread use of local anesthetic agents within the Emergency Department. It is generally a safe procedure that is technically easy to perform and well tolerated by the patient. It can be readily used for surgical procedures that are routinely performed by the Emergency Physician. This includes wound repair, foreign body removal, cutaneous abscess drainage, intravascular catheter placement, and hematoma blocks.

CONTRAINDICATIONS

The primary and most important contraindication to the use of a local anesthetic agent is a history of an allergic reaction. Less than 1% of all adverse reactions from local anesthetic agents are due to true IgE-mediated allergic phenomena.^{18,19} Ester agents are responsible for most of such cases, whereas allergic reactions to amide

anesthetics are exceptionally rare.^{7,15,20-22} The physiology behind this finding is rooted in the divergent metabolism of the two classes of local anesthetic agents.

The ester-type local anesthetic agents are rapidly metabolized within the bloodstream by serum pseudocholinesterase which explains their very short plasma half-lives. **The secondary metabolites are derivatives of the organic compound PABA. They exhibit allergenic properties and are the agents responsible for the allergic response.** This property makes ester-type local anesthetic agents (e.g., cocaine, procaine, and tetracaine) a less commonly used option in daily practice.

Amide-type local anesthetic agents are metabolized in the liver into nonallergenic byproducts via cytochrome P450-mediated pathways. Allergic reactions to the amide-type local anesthetic agents are very rare but do occur. Methylparaben is a close analog of PABA and a preservative commonly used in multidose preparations of amide agents. It may account for the rare occurrence of an apparent allergic reaction to the amide class of local anesthetic agents.^{7,15,16,22-25} **A simple way to remember if an agent is an ester or an amide is that all amides will have two "i's" in their generic name (e.g., lidocaine and bupivacaine) whereas esters only have one (e.g., procaine and tetracaine).**

An agent from the opposite class may be chosen if a history of a prior allergic reaction to an agent is obtained from a patient requiring local anesthesia. There is no true cross reactivity between the esters and the amides.⁷ Choose a preparation free of preservatives to avoid possible reactions.²³ Solutions intended for single and/or intravenous uses tend to be free of preservatives. Intravenous formulations of lidocaine can be found in any standard Emergency Department "crash cart."

Infiltration of a wound with 1% diphenhydramine is clinically effective as an alternative agent in the rare circumstance that a patient has a true IgE-mediated allergy to the local anesthetic agents.²⁶ **Diphenhydramine is more painful to inject than the local anesthetic agents and is less effective at attaining adequate anesthesia when compared to local anesthetic agents. Reserve the use of diphenhydramine for the rare instance of a patient with an actual local anesthetic allergy.**²⁶ Dilute the 5% parenteral formulation of diphenhydramine to 1% (i.e., add 1 mL of diphenhydramine to 4 mL of normal saline) to make a solution for local infiltration.

The size of the anesthetic field required for a given procedure can further dictate the utility of infiltrative anesthesia. Larger fields will require the injection of larger quantities of local anesthetic solution. **Do not exceed the maximum safe dose of a local anesthetic agent (Table 153-1). Consider an alternative anesthetic technique (e.g., regional nerve blockade or procedural sedation) if infiltrative anesthesia requires potentially toxic local anesthetic doses.** An alternative is to dilute the local anesthetic solution in half using sterile normal saline. This diluted local anesthetic solution may not provide adequate anesthesia.

TABLE 153-1 Properties and Dosages for Injectable Local Anesthetic Agents

Local anesthetic class	Anesthetic agent	Relative potency	Relative onset of action	Duration of action (minutes)*	Maximum dose without epinephrine		Maximum dose with epinephrine	
					(mg/kg)	(mg)	(mg/kg)	(mg)
Ester	Procaine (Novocain)	1	Slow	45–90	8.0	500	10.0	600
Ester	Chloroprocaine (Nesacaine)	2	Rapid	30–90	11.0	800	14.0	1000
Ester	Tetracaine (Pontocaine)	8	Slow	180–600	1.5	100	2.5	200
Amide	Lidocaine (Xylocaine)	2	Rapid	120–240	4.5	350	7.0	500
Amide	Mepivacaine (Carbocaine)	2	Rapid	180–360	5.0	300	7.0	500
Amide	Bupivacaine (Marcaine)	8	Slow	240–480	2.5	175	3.0	225
Amide	Etidocaine (Duranest)	8	Rapid	240–480	2.5	175	4.0	300

*Longer times represent the addition of epinephrine to the local anesthetic solution.

Certain procedures necessitate meticulous tissue reapproximation (e.g., facial lacerations). The injection of local anesthetic solution can distort the surrounding tissue and diminish the likelihood of an optimal outcome. Consider an alternative anesthetic technique in these situations.

Topical anesthetic agents are contraindicated on mucous membranes, the eye, denuded skin, or burned skin as they are rapidly absorbed through these tissues. Absorption can produce severe systemic toxicity and death. Eye contact can produce corneal injury. Topical agents containing cocaine and epinephrine are contraindicated in regions of end artery flow because they can result in intense vasoconstriction.²⁷ The U.S. Food and Drug Administration (FDA) has required a boxed warning against the use of prescription viscous lidocaine for infant and children teething.²⁸ Studies have shown that topical pain relievers are largely ineffective, wash out of the child's mouth rapidly, and if ingested in large enough quantities may result in complications (e.g., seizures, central nervous system [CNS] injury, and cardiac dysrhythmias).²⁹⁻³¹ Caregivers are encouraged to alleviate dental pain by using chilled teething rings or by gently massaging the affected gums with fingers.³²

EQUIPMENT

- Syringes, 1 mL to 20 mL sizes
- Needles, various sizes and lengths
- Local anesthetic solution, with or without epinephrine
- Alcohol swabs, povidone iodine, or chlorhexidine solution
- Gauze squares
- 8.4% sodium bicarbonate solution (i.e., 1 meq/mL)
- Gloves
- Face mask with an eye shield or goggles
- 5% parenteral diphenhydramine solution

Universal precautions are of utmost importance in performing any procedure using a local anesthetic agent. It is vital to wear gloves when administering topical anesthetic agents to protect the fingers, to prevent absorption of the local anesthetic agent through the fingers of the healthcare worker, and to prevent introduction of bacteria into the wound. The use of sterile as compared to nonsterile clean gloves has not been shown to alter the rate of infection for the repair of simple traumatic lacerations.³³ Nonsterile nonlatex gloves are generally sufficient for most repairs.³³ Wear a mask with a face shield or goggles to prevent accidental mucous membrane exposure if the injectable local anesthetic solution shoots out of the wound margins.

One of the most important determinants of pain response during administration of a local anesthetic agent is needle size. Use a 25 or 27 gauge needle for infiltration to minimize pain. A long needle allows for the infiltration of a larger region with a single needle pass and decreases the number of times tissues must be punctured. A 2.0 inch, 27 gauge needle is typically an optimal choice. Do not insert the needle more than two-thirds of its length to prevent inadvertent breakage within the tissues.¹³ **Another important factor is the rate of infiltration.** A slow steady method minimizes the pain response.

Many Emergency Departments have a small local anesthesia tray or basket containing the necessary equipment for providing local anesthesia. Such a kit may include the following items: needles in sizes from 18 to 30 gauge, 1 to 2 cm long, and 4 cm long; syringes ranging from 1 mL (tuberculin) to 10 mL; cotton-tipped applicators for the application of topical agents; local anesthetic agents such as 1% and 2% lidocaine, 0.25% and 0.5% mepivacaine or bupivacaine, and the same agents combined with 1:200,000 epinephrine. Sodium

bicarbonate may be used for buffering the local anesthetic agent. Alcohol swabs, povidone iodine swabs or solution, or chlorhexidine swabs or solution are required for cleansing the skin. Nonsterile and sterile examination nonlatex examination gloves are required for the infiltration of the local anesthetic agent and performing the procedure.

PATIENT PREPARATION

Discuss the procedure with the patient and/or their representative. The most common adverse reaction to a local anesthetic agent is a vasovagal reaction.¹³ This complication is more likely when patients are anesthetized while sitting in an upright position (e.g., dental procedures). The Emergency Physician must take precautions to alleviate secondary injury to the patient. Place the patient supine in a bed whenever possible with the side rails up to prevent injury no matter how minor the procedure. Friends and family members have been reported to experience syncope upon witnessing injections. Ask them to leave the room prior to starting or keep them in a sitting position throughout the duration of the procedure. Sedation (Chapter 159) can minimize the response to treatment while maintaining stable vital signs and spontaneous respirations when the patient exhibits considerable anxiety.

Prepare the area prior to injecting local anesthetic solution. Clean the skin of any dirt and debris. Apply an alcohol swab, povidone iodine, or chlorhexidine to the skin over the injection site and the surrounding area. Allow the solution to dry. Apply sterile drapes, if applicable, to delineate a sterile field.

LOCAL INFILTRATION AND PERIPHERAL NERVE BLOCKADE

LOCAL ANESTHETIC DOSING

Infiltration anesthesia refers to the injection of a local anesthetic solution directly into the subcutaneous tissues about to be manipulated. The first step to be considered is selection of the proper anesthetic. Barring a history of an allergic reaction to a given class of local anesthetic agents, the amide anesthetics lidocaine (i.e., Xylocaine) and bupivacaine (i.e., Marcaine) are the most common agents employed within the Emergency Department. Tailor the choice between these agents to the individual patient and situation. Lidocaine exhibits a quicker onset of activity whereas bupivacaine exhibits a longer duration of action (Table 153-1). Lidocaine possesses a wider margin of safety, with larger doses required to illicit a toxic response. The ester agent procaine (i.e., Novocain) is a reasonable alternative in amide-allergic patients.

It is of utmost importance to remember the maximal recommended doses for the chosen local anesthetic agent to avoid systemic toxicity (Table 153-1). The disadvantage of local infiltration is that a large volume of local anesthetic may be required for a small area. Extensive wounds may require toxic doses of local anesthetic agents to achieve adequate anesthesia. A lower concentration or the addition of epinephrine will allow a larger volume of local anesthetic to be used. Local infiltration may distort the wound edges and complicate the repair.

The maximal recommended dose of a local anesthetic agent is the same for local infiltration or regional nerve blockade. It is important to properly calculate the amount of local anesthetic agent administered to a patient. Local anesthetic solutions are supplied with the concentration denoted as a percentage (e.g., 1% lidocaine, 0.25% bupivacaine, 4% cocaine). This percentage must be converted to mg/mL. A 1% local anesthetic solution is prepared by dissolving 1 gm (i.e., 1000 mg) of the local anesthetic agent in 100 mL

of diluent. This results in a concentration of 10 mg/mL (i.e., 1 gm/100 mL = 1000 mg/100 mL = 10 mg/mL). **A simple method to calculate the strength of a local anesthetic solution is to move the decimal point one place to the right to convert from a percentage to a concentration in mg/mL (e.g., 0.25% = 2.5 mg/mL, 2% = 20 mg/mL, 4% = 40 mg/mL).** This value must be multiplied by the volume to be administered to determine the total amount in mg of local anesthetic agent. This value must be compared to the maximal allowable dose (Table 153-1) to ensure it is a safe dose.³⁴

EPINEPHRINE-CONTAINING AGENTS

Epinephrine can be added to a local anesthetic solution to **prolong its duration of action, to assist with hemostasis by local vasoconstriction, and to slow the absorption of the local anesthetic agent.** This allows for larger quantities of local anesthetic solution to be injected and diminishes the concern for systemic toxicity. Local anesthetic agents generally compounded with epinephrine in a 1:100,000 or 1:200,000 solution are available from the manufacturer.

One can be readily formulated if a compounded solution is not available. Begin by obtaining 1:1000 epinephrine, which is usually administered to patients for severe allergic reactions or bronchospasm. This solution of 1:1000 contains 1 gm of epinephrine per 1000 mL or 1 mg/mL of epinephrine. Diluting this solution by a factor of 100 will result in the desired 1:100,000 concentration. Place 0.1 mL of 1:1000 epinephrine into 10 mL of local anesthetic solution to make a dilution of 1:100,000 or 0.010 mg/mL. Place 0.1 mL of 1:1000 epinephrine into 20 mL (i.e., 0.05 mL in 10 mL) of local anesthetic solution to make a dilution of 1:200,000 or 0.005 mg/mL.

REDUCING THE PAIN OF INFILTRATION

Local anesthetic agents are weak bases. They are packaged as hydrochloride salts with a pH of 4 to 6 to increase their solubility and shelf life. This acidic pH causes much of the pain associated with the injection of local anesthetic agents.^{4,6} Epinephrine is unstable at a physiologic pH. Commercial solutions containing epinephrine are generally formulated with similarly acidic pH values. **Buffering lidocaine, mepivacaine, or bupivacaine with sodium bicarbonate has been shown to reduce the pain of injection significantly.**^{27,35,36} Raising the pH of the local anesthetic agent increases the percentage of local anesthetic molecules in the nonionized diffusible state.³⁵ This may allow nearly instantaneous penetration of the nerve cell membrane by the anesthetic molecules and block or reduce the pain of infiltration.^{35,37,38} **Buffering local anesthetic agents does not affect the duration of anesthesia, degree of anesthesia, the serum levels of the local anesthetic agent, or the toxicity of buffered anesthetic agents.**

Caution must be exercised when buffering highly lipophilic and less soluble anesthetic agents (e.g., bupivacaine) because precipitation can occur.⁴ Use the prepackaged 50 mL ampules of 8.4% (i.e., 1 meq/mL) sodium bicarbonate found in any “crash cart.” Add 1 mL of 8.4% (i.e., 1 meq/mL) sodium bicarbonate to 10 mL of 1% lidocaine or 1% mepivacaine, with or without epinephrine, to achieve buffering.³⁵ Add 0.05 to 0.10 mL of 8.4% (1 meq/mL) sodium bicarbonate to each 10 mL of 0.5% bupivacaine.³⁶

The use of warm lidocaine [37°C (98.6°F) to 42°C (107.6°F)] decreases the pain of infiltration.³⁹⁻⁴¹ The exact etiology of this is unknown. It is hypothesized that warm lidocaine does not stimulate cold receptors and diffuses into tissues faster. Warm the local anesthetic agent by placing it in a blanket warmer or a water bath. The combination of warming and buffering a compound results in an even less painful procedure.^{40,42}

Other simple measures can help reduce the pain of the local anesthetic injection. Limit the infiltration of a local anesthetic solution

FIGURE 153-1. The needle is inserted through the wound edge to inject local anesthetic solution.

to the subdermal space. This will help decrease the overall pain of injection, minimize the degree of tissue distortion, and protect the patient from the inadvertent injection into an intravascular space. Make every attempt to infiltrate through the exposed wound edges rather than puncturing through the adjacent intact skin when anesthetizing an open wound (**Figure 153-1**).⁴³ This will provide a much less painful experience for the patient. Infiltrate grossly contaminated wounds percutaneously through clean and intact skin to decrease the risk of spreading the contamination and to decrease the risk of an infection related to the infiltration (**Figure 153-2**). Limit the number of needle punctures through uninjured skin in contaminated wounds. The application of gentle pressure to the injection site prior to the injection (e.g., pressing a sterile cotton tipped applicator against the skin) limits the pain associated with childhood vaccinations.⁴⁴ Dentists have been using similar distraction techniques for many years to perform dental blocks. The use of this technique in the Emergency Department is limited by the fact that infiltrations into previously inflamed tissue and secondary stimulation may expose the patient to unwarranted additional pain. A slower rate of local anesthetic solution injection is associated with less pain.

Insert the needle into an open wound at its apex (**Figure 153-2**). Tunnel the needle its entire length down the wound margin. Inject

FIGURE 153-2. The needle is inserted through the intact skin to inject local anesthetic solution.

the local anesthetic solution while slowly withdrawing the needle. Do not completely withdraw the needle from the skin. Redirect it along the opposing wound margin and repeat the technique. This can be performed down the entire length of the wound as necessary. Minimizing the number of skin punctures will help to minimize pain.

In summary, the pain upon injection of local anesthetic agents can be reduced by following a few simple suggestions.^{45,46} Warm and/or buffer the local anesthetic agent. Inject the local anesthetic agent slowly. Inject open wounds through the wound edges and not through intact skin except when the wound is grossly contaminated. Infiltrate subdermally to minimize pain and tissue distention. Insert and advance the needle to create a tract and inject as the needle is withdrawn to minimize tissue distention. Do not totally withdraw the needle after infiltration when possible. Leave the tip of the needle within the skin and redirect the needle to prevent excessive skin punctures.

COMBINING LOCAL ANESTHETIC AGENTS

Physicians have combined various local anesthetic agents to exploit the unique properties of each individual local anesthetic agent, to achieve a rapid onset, and to achieve a prolonged duration of action.^{47,48} The rapid-acting lidocaine can be safely mixed in a 1:1 ratio with longer acting but slower onset bupivacaine. Employing this mixture may be no more dangerous than sequentially administering equal doses of either parent compound. **The value of such an approach is questionable.** Enough concern persists regarding the potential toxicity of this mixture to often preclude its use within the Emergency Department. The combined benefits might not be as relevant within the Emergency Department as most studies referenced come from the anesthesia and surgical literature.

It is important to recognize that the toxic effects in an overdose situation are additive, even if an amide and ester are combined.^{49,50} Mixing two local anesthetic agents can complicate the overall dosage calculations and enhance the potential for a toxic injection. **It is difficult to determine the maximum dose if two local anesthetic agents are mixed together.** It will be impossible to determine which of the two anesthetics is the causative agent if the patient develops an allergic reaction. **The combination of local anesthetic agents cannot currently be recommended as general practice. Use lidocaine containing epinephrine, bupivacaine, or bupivacaine containing epinephrine to prolong the anesthetic effect rather than combining two local anesthetic agents.**

ALTERNATIVE TECHNIQUES

It has been known since the 1940s that injected antihistamines exhibit anesthetic properties. A 1956 study comparing the infiltration of diphenhydramine to procaine demonstrated equal anesthetic properties. Subsequent Emergency Medicine-based studies have shown equal anesthetic results when comparing the injection of 1% solutions of either lidocaine or diphenhydramine, although the latter was associated with a more painful infiltration. A further study comparing 0.5% diphenhydramine to 1% lidocaine demonstrated resolution in the disparity regarding the pain of injection, albeit at the expense of creating a disparity in the anesthetic effect.⁵¹ **The overall duration of anesthesia produced by infiltrated diphenhydramine is shorter than that of lidocaine.** A concern has arisen regarding the possible destruction of local tissue and subsequent skin necrosis associated with diphenhydramine infiltration. Multiple early experiences had reported this complication. An appropriate dilution prior to injection eliminates this potential complication. Dilute 1 mL of standard parenteral 5% diphenhydramine solution with 4 mL of sterile normal saline to achieve a 1% solution that is suitable for injection.^{52,53} **Consider diphenhydramine a viable**

alternative to the more commonly used local anesthetic agents when they are contraindicated.

LIPOSOMAL BUPIVACAINE

Liposomal bupivacaine (Exparel) is a long-acting form of bupivacaine. This formulation slowly releases bupivacaine from liposomes, thereby delaying the peak plasma concentrations and increasing the duration of action with a half-life of greater than 24 hours. It is approved by the U.S. FDA for pain relief by local infiltration in post-surgical patients. The preponderance of data is specifically for bunionectomy and hemorrhoidectomy surgeries. Studies have shown it to be effective for postoperative pain relief with opioid-sparing effects. It has been found to have an acceptable adverse effect profile.

Liposomal bupivacaine can be administered undiluted or diluted to increase volume up to a concentration of 0.89 mg/mL (i.e., 1:14 dilution by volume) with normal saline or lactated Ringer's solution. The dosing in the trial for a bunionectomy was a total of 8 mL or 106 mg administered as 7 mL infiltrated into the tissues surrounding the osteotomy and 1 mL infiltrated into the subcutaneous tissue.⁵⁴ The dosing in the trial of hemorrhoidectomy surgery was a total of 20 mL or 266 mg with 10 mL of saline divided into six 5 mL aliquots injected by visualizing the anal sphincter as a clock face and slowly infiltrating one aliquot to each of the even numbers to produce a field block.⁵⁵

Different formulations of bupivacaine are not bioequivalent. It is not possible to convert dosing from any other formulations of bupivacaine to liposomal bupivacaine. Non-bupivacaine-based local anesthetics may cause an immediate release of bupivacaine from Exparel if administered together locally. The administration of liposomal bupivacaine may follow the administration of lidocaine after a delay of 20 minutes or more.⁵⁶

Dosing recommendations and the preparations of the product for local infiltration in nonsurgical procedural cases have not been established. The use of liposomal bupivacaine has not been evaluated in pediatric patients or in pregnancy. More studies are needed to establish the safety and efficacy for liposomal bupivacaine in epidural or intrathecal use, regional nerve blocks, and intravascular or intraarticular use. The application of liposomal bupivacaine in Emergency Department practice cannot be recommended, although it could prove to be a useful adjunct in the very near future.⁵³

ASSESSMENT

It is important to wait long enough after the local anesthetic agent is administered to allow the onset of adequate anesthesia before the planned procedure is started. A period of 5 to 10 minutes is usually adequate for subcutaneous local infiltration. A period of 15 to 30 minutes may be required for peripheral nerve blocks. A simple examination of the area being anesthetized with fine touch and pinprick is important to ensure adequate anesthesia prior to the procedure. It may be necessary to inject additional local anesthetic solution in areas of continued sensitivity while keeping in mind the total dose injected to avoid toxicity.

AFTERCARE

Observe the patient for a minimum of 15 minutes following the use of local anesthesia to assure no evidence of an adverse reaction. The length of time analgesia is maintained depends upon the agent used for the procedure (**Table 153-1**). The patient need not wait in the Emergency Department for normal sensation to return prior to discharge. They should be instructed to return to the Emergency Department if normal sensation has not returned within 12 to 24 hours.

COMPLICATIONS

Toxic reactions to local anesthetic agents are far more common than allergic sequelae.^{13,17,57} The propensity for toxicity is directly proportional to the potency of the drug.^{7,9,11} **Table 153-1** lists the recommended maximal doses for commonly used local anesthetic agents. **These are only estimates, and in certain circumstances, the toxic dose may be considerably less.^{7,21} Infiltration into highly vascular areas, inadvertent intravascular injection, or application to mucous membranes may cause toxicity at accepted standard doses.⁷**

It is unlikely that toxic serum concentrations of local anesthetic agents will be reached in most clinical situations in the Emergency Department. For example, the maximum dose of 1% lidocaine without epinephrine in a 70 kg patient would be approximately 31.5 mL. This is a volume that is more than adequate for most wounds. **It is important to be vigilant of the total dose administered, especially in patients with large or multiple lacerations in whom higher doses of local anesthetics may be required.** A less concentrated form of the local anesthetic agent (e.g., 0.5% lidocaine as opposed to 1%) may be used when the maximum dose could be exceeded; however, this may decrease the degree of anesthesia. Procedural sedation (Chapter 159) at the bedside or general anesthesia in the Operating Room may be required to repair larger wounds.

The major manifestations of local anesthetic toxicity occur in the CNS and the cardiovascular system.^{6,9,13,15} Initial signs and symptoms are of CNS excitation. This occurs from the suppression of inhibitory cortical neurons and leads to unopposed functioning of facilitatory pathways. Signs and symptoms include ataxia, delirium, disorientation, dizziness, lightheadedness, nystagmus, psychosis, restlessness, sensory disturbances (e.g., visual difficulties, tinnitus, perioral tingling, metallic taste in the mouth), unconsciousness, and an unsteady gait.⁵⁸⁻⁶⁰ Muscle twitching, slurred speech, and/or tremors may immediately precede seizures. There may also be augmentation of medullary and sympathetic activity with resultant hyperpnea, hypertension, tachycardia, and tachypnea. Generalized depression of the entire CNS can occur and is manifested as coma, drowsiness, and ultimately respiratory arrest.^{9,15}

Management of CNS toxicity should begin with an assessment of the patient's airway, breathing, and circulation. Treatment is primarily supportive. Hypoxia and acidosis enhance CNS and myocardial absorption of local anesthetic agents and must be addressed aggressively. Hypocapnia raises the seizure threshold to prevent convulsions by inducing cerebral vasoconstriction and by decreasing the delivery of the local anesthetic agent to the CNS.^{7,61} An alert and cooperative patient may be instructed to hyperventilate if early signs of toxicity are present.^{6,21,62} Manage seizures with intravenous benzodiazepines to raise the CNS threshold to local anesthesia-induced convulsions. The metabolism of local anesthetics is short enough that loading patients with long-acting antiepileptic drugs (e.g., phenytoin) is generally not required. The effect of phenytoin upon sodium channel conduction can potentiate the arrhythmogenic property of local anesthetics. Administer short-acting neuromuscular blocking agents (e.g., succinylcholine or vecuronium) until serum levels of the local anesthetic agent decline if the seizures fail to respond to benzodiazepines.⁷ Succinylcholine is metabolized by pseudocholinesterase. This is the same plasma enzyme that metabolizes ester anesthetic agents. Avoid succinylcholine in ester-induced seizures.^{7,6,21}

The cardiovascular system is relatively resistant to local anesthetic toxicity in comparison with the CNS.^{17,25} The cardiovascular system does not exhibit toxicity until much higher blood levels are reached.^{17,25} Cardiovascular toxicity results from the direct effects upon cardiac and vascular smooth muscle and the indirect effects upon autonomic tone. Complications are the result of

negative inotropism, peripheral vasodilatation, and slowing of the myocardial conduction system.^{9,15} Arterial dilation combined with decreased cardiac contractility leads to progressive hypotension and eventual cardiovascular collapse. The sodium and calcium channel blockade exhibited at more toxic doses predisposes the patient to fatal arrhythmias. The end results are hypotension, bradycardia, prolonged electrocardiographic intervals, and eventually cardiac arrest.^{9,11,15} Treatment is supportive with inotropes, intravenous fluids, and vasopressors. Avoid class IB antidysrhythmics (e.g., lidocaine, mexiletine, and tocainide) due to their potential to accentuate cardiac sodium channel blockade. Vasopressors with positive inotropic effects (e.g., dopamine) will treat profound cardiovascular depression.⁷

Bupivacaine is more cardiotoxic than other local anesthetic agents. Treatment of bupivacaine cardiotoxicity has shown a potential benefit with the use of high-dose intravenous insulin (e.g., 2 IU/kg) in concert with supplemental intravenous glucose and intravenous potassium boluses.⁶³ The infusion of a lipid emulsion (i.e., Intralipid) has also been proposed for use in bupivacaine, levobupivacaine, lidocaine, and ropivacaine.⁶⁴⁻⁷⁶ The actual mechanism of action is unclear. Hypotheses include the extraction of lipophilic anesthetics from their target tissues via the fatty emulsion and/or the direct antagonization of anesthetic-mediated suppression of cardiac fatty acid metabolism.^{77,78} Always attempt the rescue interventions with ongoing Advanced Cardiac Life Support protocols.

Treatment of symptomatic local anesthetic toxicity involves a large initial IV bolus of 20% lipid emulsion at 1.5 mL/kg over 1 minute followed by an IV drip of 0.25 mL/kg/min.^{64,79} Use ideal body weight to calculate the dose. The bolus can be repeated two times at 5 minute intervals and the drip rate doubled. Continue the drip at 0.025 mg/kg/min as needed for up to 6.5 hours. The maximum total dose of Intralipid administered should not exceed 12 mL/kg.⁷⁸ Consultation with a Toxicologist is recommended. Although the lipid-based drug propofol is often more readily available in the Emergency Department than Intralipid, the former is compounded in a 10% lipid solution. **The volume of propofol solution needed to reverse local anesthetic toxicity requires the administration of a toxic dose of propofol and is therefore contraindicated.⁸⁰⁻⁸² Intralipid administration is strictly contraindicated in any patient with soy or egg allergies.**

Intralipid also comes in a 30% emulsion.^{74,83} The dosing is different from the above 20% emulsion. Administer the 30% emulsion in a bolus of 1 mg/kg over 1 minute followed by an infusion of 10 mL/kg/h over 15 minutes. The bolus can be repeated two times at 5 minute intervals and the drip rate doubled. The maximum total dose of Intralipid administered should not exceed 6 mL/kg.^{74,83}

Adding epinephrine to a local anesthetic agent increases both the amount of drug that can be administered and the duration of action.^{4,14} It decreases bleeding into the surgical field. There are significant drawbacks to the use of epinephrine. These include increased pain of infiltration, increased wound inflammation, increased wound infection rates, increased uncomfortable side effects in susceptible patients (e.g., palpitations, tremors, syncope), and the potential for severe tissue ischemia if used in regions of end arterial circulation.¹³ Emergency medicine dogma cautions against the use of an epinephrine-containing local anesthetic agents in regions of end arterial circulation (e.g., digits, the tip of the nose, the pinna, or the penis) to avoid potential distal tissue infarction and necrosis.⁸⁴ The clinical evidence supporting this concern is scant and the little that does exist is dated. Reviews of digital nerve blocks performed with epinephrine found no cases of digital necrosis or gangrene.⁸⁵⁻⁸⁷ Most of these studies were carried out in healthy patients without peripheral vascular disease. The few studies carried out in patients with poor circulation did not demonstrate any adverse effects from using epinephrine.^{85,87} Current practice guidelines suggest that the danger of using epinephrine in extremities is likely overstated and

any appreciable vasoconstriction is transient.⁸⁸ Literature focused on the inadvertent infiltration of epinephrine into fingers via improperly used autoinjectors has similarly failed to demonstrate a single significant case of tissue necrosis.⁸⁹ Most of these cases demonstrated a spontaneous return of perfusion with only conservative treatments (i.e., warm soaks and digital massage). Prolonged vasospasm and ischemia in these areas can be reversed with the subcutaneous infiltration of 1.0 mL of 1:1000 phentolamine (i.e., 1 mg) diluted with saline in a 1:1 mixture at the local anesthetic injection site.⁹⁰⁻⁹⁴ A less invasive alternative is to apply topical nitroglycerin paste to the affected area. Caution must be used when administering epinephrine to patients who are elderly, are taking beta-blockers, or have a history of coronary artery disease, hypertension, hyperthyroidism, or pheochromocytoma.^{6,13} Inadvertent intravascular injection of epinephrine can have fatal consequences.^{95,96}

The potential systemic complications unique to epinephrine are not often an issue. One must infiltrate 30 mL of local anesthetic solution to attain a cumulative dose of 0.3 mg using 1:100,000 preparations, a quantity commonly used subcutaneously for anaphylactic allergic reactions. Such a large volume is rarely encountered with infiltrative anesthesia. Consider an alternative anesthetic technique if a large volume of local anesthetic solution containing epinephrine is required. Rare reports of patient mortality secondary to an inadvertent intravenous injection have been reported. Use extreme care when using these preparations in any patient with suspected cardiovascular disease.

True allergic reactions are rare adverse events.¹⁹ Effective management of an allergic reaction depends upon its severity and may include the use of epinephrine, antihistamines, steroids, and vasopressors. A complete review of the management of allergic reactions and anaphylaxis can be found in standard Emergency Medicine textbooks.

A rare but acute nonallergic type of reaction to lidocaine is called Hoigne syndrome. It is characterized as a “doom anxiety” and is a non-dose-dependent primarily psychiatric reaction to lidocaine.⁹⁷ Patients may complain of anxiety, lightheadedness, palpitations, and feeling like they are about to die. There are various theories as to the pathophysiology of Hoigne syndrome. The exact mechanism is still unknown. Treatment is supportive and standard benzodiazepine administration is usually sufficient. The condition is self-limited and patients may be discharged home once symptoms resolve. Warn the patient that they may experience subsequent anxiety, bad dreams, or muscle tension for up to 7 days after the initial inciting reaction.⁹⁷

Methemoglobinemia has been reported to occur following the use of both classes of local anesthetic agents.⁹⁸⁻¹⁰² It is most commonly seen after the use of the topical agent benzocaine.⁹⁸⁻¹⁰² The use of this medication is discussed elsewhere in this book. The Emergency Physician must be aware of this potential complication and intervene appropriately. **Methemoglobin is an altered state of hemoglobin where the ferrous (i.e., Fe²⁺) irons of heme are oxidized to the ferric (i.e., Fe³⁺) state.** The ferric irons are unable to bind oxygen, resulting in impaired oxygen delivery to tissues.

Initial methemoglobinemia is characterized by a cyanotic-looking appearance and low oxygen saturation that does not respond to supplemental oxygen. Patients may complain of dizziness, dyspnea, exercise intolerance, fatigue, headache, and weakness when methemoglobin levels reach approximately 20% or more. Serious complications (e.g., chest pain, CNS depression, dysrhythmias, seizures, and tachypnea) occur at methemoglobin levels above 50%. Death is associated with methemoglobin levels exceeding 70%. Patients with preexisting anemia may become symptomatic at lower methemoglobin levels due to an already reduced oxyhemoglobin concentration.¹⁰³

Other topical anesthetics besides benzocaine (e.g., Hurricane spray) that may induce methemoglobinemia include benzocaine/tetracaine/butamben (e.g., Cetacaine) and lidocaine plus prilocaine (e.g., EMLA cream).¹⁰⁴⁻¹⁰⁶ Formation of methemoglobin from these products is dose-dependent. Emergency Physicians are advised to strictly follow the age-based dosing recommendations and the maximum dose recommendations.

First-line treatment of methemoglobinemia is intravenous administration of methylene blue at a dose of 1 to 2 mg/kg over 5 minutes. Administer treatment to symptomatic patients with methemoglobin levels greater than 10% to 15%. Treat all patients with methemoglobin levels greater than 25% regardless of symptoms.¹⁰⁷

Injection of local anesthetic agents can cause complications. These agents have not been shown to increase the incidence of wound infections. Do not inject local anesthetic agents into a joint prior to obtaining synovial fluid. They can result in false-negative culture results, false-negative crystal analysis due to dissolving crystals, and false-positive crystal analysis due to anesthetic crystal formation. Needle punctures of arteries, nerves, and veins are usually a temporary inconvenience with no long-lasting consequences. Intraneural injection can result in temporary or permanent nerve injury. **Never inject local anesthetic agents if the patient experiences paresthesias indicating intraneural needle placement.** Withdraw the needle 1 to 2 mm and allow the paresthesias to resolve before infiltrating with the local anesthetic solution. Never redirect the needle when more than the tip is subcutaneous to prevent needle breakage.

SUMMARY

Local anesthetic agents have become an indispensable tool in the practice of Emergency Medicine. Emergency Physicians often rely on local anesthetic agents to relieve patient discomfort and provide wound care. Infiltrative anesthesia represents one of the most prevalent uses for these agents. It is relatively quick, easy to perform, well tolerated, and has a large margin of safety. Complications can and do arise. The Emergency Physician must be ready to recognize the warning signs of local anesthetic toxicity and intervene appropriately. In-depth knowledge of the appropriate administration of these common agents plays an important role in the practice of medicine. Emergency Physicians have sought to relieve the pain and suffering of our patients. These agents allow us to come closer to attaining that goal.

Topical and Noninvasive Anesthesia

Sonali Gandhi and Michael Schindlbeck

INTRODUCTION

Invasive procedures can cause significant anxiety in patients both young and old, much of which is related to fear of the associated pain. Noninvasive anesthesia has been shown to decrease pain and anxiety surrounding procedures (e.g., lumbar puncture, intravenous access, and laceration repair).^{1,2} This chapter will discuss topical anesthetic agents, noninvasive anesthetic agents, and the range of techniques that are available for delivery of these agents. Not discussed are many of the nonpharmacologic techniques to decrease pain and anxiety except oral sucrose.³⁻¹⁰

ANATOMY AND PATHOPHYSIOLOGY

Mechanical, thermal, and chemical stimuli are detected by nerve endings called nociceptors. These pain receptors are in the dermis and the epidermis of the skin (**Figure 154-1**). Nociceptors are free nerve endings that have their cell bodies outside the spinal column in the dorsal root ganglia. The intact stratum corneum, the outer layer of cornified epithelial cells of the skin, is an effective barrier to the outside environment. Local anesthetics must traverse the stratum corneum to be delivered to the terminals of cutaneous sensory nerve fibers. The local anesthesia can block or reduce the action potential of the nerve fibers and prevent depolarization of the nerve ending. The three methods by which the stratum corneum can be bypassed to deliver a local anesthetic are direct injection, passive diffusion, and needle-free drug delivery strategies. This chapter will focus on the techniques for enhancing passive diffusion and needle-free administration of local anesthetic agents, collectively known as topical anesthesia.

INDICATIONS

Topical anesthesia is commonly utilized in the Emergency Department. The patient experiencing pain from an injury (e.g., a laceration, abrasion, or contusion) can benefit from the application of topical anesthesia. The use of topical anesthesia is beneficial in the patient who will undergo a painful procedure (e.g., venipuncture, lumbar puncture, abscess incision and drainage, or laceration repair).^{11,12}

Topical anesthetic agents offer several potential advantages over local infiltration anesthesia. They are less painful to apply, overcome aversions toward needles, do not distort the wound margins, decrease the infection rate, are easy to use, and decrease the need for sedation.² The major limitations of topical anesthesia have been the extended time required to achieve anesthesia (**Table 154-1**) and the lack of sufficient analgesia that often requires supplemental infiltration anesthesia. These constraints have limited the use of topical

FIGURE 154-1. Cross-section of skin showing cornified stratum corneum surface with underlying sensory nerve endings.

anesthesia in the Emergency Department. Several new agents and delivery techniques have addressed these limitations with some success, offering the Emergency Physician more options for providing anesthesia.

CONTRAINDICATIONS

There are very few contraindications to the use of topical anesthetics. The topical anesthetic agent is typically not systemically absorbed to any significant degree. They can cause local adverse reactions and should not be used in patients who are allergic to the medication or its components (e.g., preservatives). **Use care when applying topical anesthetics to mucous membranes. Absorption from mucous membranes is typically more rapid and efficient than through skin, and more substantial systemic absorption can occur.** A relative contraindication to using topical anesthetic agents are patients taking class I antiarrhythmics (e.g., mexiletine and tocainide) as they can produce additive and possibly toxic effects. Many of the topical anesthetics are contraindicated or require special ophthalmic formulations for use in the eye. **Special care and attention to dosing is imperative in neonatal patients to avoid toxicity.** Specific contraindications and concerns for each topical agent and application technique are addressed later in this chapter and Chapter 153. Use caution if the patient is taking medications that may cause methemoglobinemia (**Table 154-2**).¹³

Do not use lidocaine products on the oral mucosa of patients less than 3.5 years of age for relief of teething and stomatitis pain.¹⁴⁻¹⁶

Young children can swallow these preparations instead of swishing and spitting them out. Swallowing can cause serious adverse reactions, seizures, and death.

EQUIPMENT

GENERAL SUPPLIES

- Alcohol swabs
- Povidone iodine or chlorhexidine solution
- Gauze squares, 2×2 and 4×4
- Gloves

TOPICAL CREAM, GEL, OR LIQUID

- TAC (i.e., 0.5% tetracaine, 1:2000 epinephrine, and 11.8% cocaine)
- LET (i.e., 0.5% tetracaine, 1:2000 epinephrine, and 4% lidocaine)
- EMLA (i.e., 2.5% lidocaine and 2.5% prilocaine)
- LMX-4 or LMX-5 (i.e., 4% or 5% liposomal lidocaine)
- Topicalaine (i.e., 4% lidocaine gel)

IONTOPHORESIS

- 2% lidocaine hydrochloride containing 1:100,000 epinephrine
- Device to administer iontophoresis (**Figure 154-2**)
- Iontophoresis system

TABLE 154-1 Characteristics of Topical Anesthetic Agents

Medication or method	Time to anesthesia (minutes)	Duration of anesthesia (minutes)	Dose	Side effects
Amethocaine	30–45	240–360 after removal	1 tube covers up to 30 cm ² < 1 month: do not use 1 month–5 years: 1 tube 5 years of age: 2 tubes Adults: 7 tubes	Local skin reaction
EMLA (eutectic mixture of lidocaine and prilocaine)	60 superficial dermal, 120 deep dermal	60 after removal (shorter in more vascular areas)	0–3 months or < 5 kg: 1 gm/10 cm ² body surface area (BSA) for 1 h 3–12 months and > 5 kg: 2 gm/20 cm ² BSA for 4 h 1–6 years and > 10 kg: 10 gm/100 cm ² BSA for 4 h 7–12 years and > 20 kg: 20 gm/200 cm ² BSA for 4 h	Local skin reactions
Heat-enhanced diffusion patches (Synera or Rapydan)	10–30	100 after removal	1 patch for > 3 years of age	Local skin reactions
Iontophoresis with lidocaine with epinephrine	10–20	30–45	Calculate dosage	Burns, local skin reactions
Jet lidocaine injection	1–3	45	Inject area, calculate dosage	Contusions, minor bleeding, cellulitis, administration pain
Laser-assisted transdermal	5	30–45	Calculate dosage	Local skin reactions, administration pain
LET (lidocaine, epinephrine, and tetracaine)	15–30	45–60	Apply 1–3 mL to open wound	None
Lidocaine gel 4% or 5% (Topicalaine)	20–60, mean 30	20–60	Apply 1/8 inch thick layer in 2 year olds and older	Local skin reactions
Liposomal lidocaine (LMX-4 and LMX-5)	30	60 after removal	1 gm/10 cm ² BSA. Do not apply > 1 gm in < 1 year of age. Do not leave on > 1 h in < 3 months of age, > 4 h in 3–12 months of age, > 5 h in 12 months of age and older. Do not use in those < 1 month of age	Skin erythema
Peels (S-Caine and Pliaglis)	20–60	600+	Only use in adults. Apply a thin layer	Local skin reactions
Powdered lidocaine injector	1–3	10–20	Inject once to intact skin	Contusions, minor bleeding, cellulitis
TAC (tetracaine, adrenaline, and cocaine)	20–30	45–60	Apply 1–3 mL to open wound. Avoid mucous membranes	Seizures, cardiac arrest (rare)
Ultrasound-assisted delivery	5	30–45	Calculate dosage	Local skin reactions
Vapocoolant sprays	0.1–0.2	1	Use in 3 years or older	Frostbite, skin erythema

■ ULTRASOUND-ASSISTED LOCAL ANESTHETIC DELIVERY

- Ultrasound device (**Figure 154-3**)
- Topical local anesthetic agent

■ POWDERED ANESTHETICS

- Needle-free powder lidocaine delivery system (**Figure 154-4**)

■ LIDOCAINE NEEDLE-FREE INJECTION

- Needle-free injection system, prefilled or fillable (**Figure 154-5**)
- 1% or 2% lidocaine

TABLE 154-2 Some of the Medications that Can React with Topical Anesthetics and Cause Methemoglobinemia

Acetaminophen	Nitrites
Aniline dyes	Nitrofurantoin
Benzocaine	Nitroglycerine
Chloroquine	Phenobarbital
Cyclophosphamide	Phenyton
Dapsone	Prilocaine
Flutamide	Primaquine
Lidocaine	Procaine
Mesalamine	Sodium nitroprusside
Naphthalene	Sulfonamide
Nitrates	Trimethoprim-sulfamethoxazole

■ HEAT-ENHANCED DIFFUSION

- Lidocaine-tetracaine thermal patch (**Figure 154-6**)

■ LASER-ASSISTED TRANSDERMAL PASSAGE

- Cutaneous resurfacing laser (**Figure 154-7**)
- Topical anesthetic agent

■ TOPICAL VAPOCOOLANT SPRAYS

- Topical vapocoolant spray (**Figure 154-8**)

PATIENT PREPARATION

Discuss the procedure and its risks, benefits, complications, and alternatives with the patient and/or their representative. Obtain an informed consent for the procedure and place this in the medical record. When performing the procedure on a neonate or child, it is advisable to give the parent the option to leave the room or look away as the procedure can be disconcerting to some parents.

Use precautions to prevent further injury or pain to the patient. Cleanse the skin of any dirt and debris. This will aid in providing appropriate anesthesia to the affected area.¹⁷ Apply povidone iodine or chlorhexidine solution to the skin and allow it to dry. Consider administering a supplemental anxiolytic or procedural sedation (Chapter 159).

Young children do not talk and are afraid of any procedures performed. Their actions demonstrate anxiety and pain (**Table 154-3**). There are several methods described to characterize the child's pain.¹⁸

PASSIVE DIFFUSION OF LOCAL ANESTHETIC AGENTS

Topical local anesthetic agents are often applied in the form of a gel or cream.^{19,20} There are numerous combinations of anesthetic agents to use topically on wounds. TAC (i.e., tetracaine, adrenaline, and cocaine), LET (i.e., lidocaine, epinephrine, and tetracaine), and EMLA (i.e., eutectic mixture of lidocaine and prilocaine) are three commonly applied combinations (**Table 154-1**). Other topical local anesthetic agents include lidocaine gel and liposomal lidocaine.

FIGURE 154-3. The Sontra Sonoprep ultrasound-assisted anesthetic delivery unit. (Photo courtesy of Sontra Medical Corp., Franklin, MN.)

TAC

Many Emergency Departments use TAC for topical anesthesia. It is a combination of 0.5% tetracaine, 1:2000 or 0.05% adrenalin (i.e., epinephrine), and 11.8% cocaine. TAC provides topical anesthesia and vasoconstriction. The vasoconstrictor action reduces blood flow in the affected area and systemic absorption of the drug. The degree of anesthesia achieved with TAC is comparable to that of local lidocaine infiltration for wounds on the face and scalp. TAC is superior to lidocaine infiltration in pediatric patients, which research attributed to patient compliance.^{21,22} The effects are less profound for wounds on the trunk and extremities.

The cocaine component in TAC is a powerful and effective local anesthetic agent and a vasoconstrictive agent. **TAC is a controlled substance.** This makes its storage, utilization, and monitoring subject to stringent regulation and documentation requirements. This may limit the availability and use of TAC in some institutions.

Dose recommendations generally call for 5 mL of TAC for lacerations smaller than 3 cm in length and 10 mL for lacerations greater than 3 cm in length.²³ Apply the chosen volume of TAC liquid or gel onto a 2×2 gauze square or a cotton ball. Invert the gauze square or cotton ball to apply TAC within the wound margins. Allow TAC to remain for up to 15 minutes or until visible skin blanching occurs. **Blanching indicates the presence of vasoconstriction and adequate analgesia.** The gauze pad can be held in place by the patient's gloved hand, the patient representative's gloved hand, or with tape.

TAC is not free of complications. **Always wear gloves when handling TAC to prevent percutaneous absorption.** Do not apply TAC to tissues with an end-arteriole supply due to the vasoconstrictive effects of cocaine. This includes the fingers, toes, nose, ear, and penis. There is the possibility of vasoconstrictive ischemic injury to these tissues. The systemic absorption of cocaine from TAC

(Photo courtesy of ZetaJet, Malvern, Australia.)

administration has been implicated in rare episodes of respiratory arrest, seizures, and death.^{24,25}

LET

LET is an alternative to TAC.²⁶ It is a combination of 4% lidocaine, 0.1% (1:1000) adrenaline (i.e., epinephrine), and 0.5% tetracaine.²⁷ It is considered safer, similarly effective, more practical, and more

FIGURE 154-6. The Synera lidocaine-tetracaine patch. (Photo courtesy of Galen US Inc., Souderton, PA.)

cost effective to use than TAC. No statistical significance was found between anesthesia for pediatric and adult patients using LET compared to TAC on the face and scalp for uncomplicated lacerations.^{27,28} **LET does not contain a controlled substance and has no potential for abuse.**^{26,27} The resultant security and documentation requirements are much less complicated than those required for TAC.

Apply liquid LET by dripping it into the wound or taping a LET-soaked cotton ball or 2×2 gauze square over the wound. Allow it to dwell 20 to 30 minutes or until the wound edges blanch. The addition of methylcellulose to liquid LET makes a gel that is more adherent and can be painted on wounds. The gel form will not drip or run. Common guidelines suggest it should not be placed on the digits, ear, nose, penis, or other areas that are supplied by end arteries

FIGURE 154-8. Gebauer vapocoolant spray. **A.** Spray bottle. **B.** Aerosolized can.

due to the strong vasoconstrictive effect and risk of ischemia. These guidelines are currently being challenged.²⁹ It can be used for lacerations on all other locations except those grossly contaminated.²⁰

EMLA CREAM

The use of EMLA (i.e., eutectic mixture of local anesthetics) cream has gained significant popularity, particularly in pediatric patients. It is an emulsion of 2.5% lidocaine and 2.5% prilocaine in a 1:1 ratio by weight. Each gram of EMLA contains 25 mg of lidocaine and 25 mg of prilocaine. It is nonsterile and preservative free. It is also commercially available in prepackaged transdermal disks. **Apply EMLA only onto intact skin and not into open wounds.** It is not licensed for use in injured or violated skin.

TABLE 154-3 Pain Signs and Symptoms in Preverbal Children	
Back arching	Increase in respiratory rate
Changes in facial expression	Limb thrashing
Finger clenching	Oxygen desaturation
Flushing	Pallor
Head banging	Poor feeding
Increase in blood pressure	Sleep disturbances
Increase in heart rate	Sweating
Increase in muscle tone	Writhing

EMLA is indicated prior to venipuncture, arterial punctures, access of indwelling ports and reservoirs, lumbar puncture, minor skin procedures, tympanic membrane and external auditory canal anesthesia, or regional nerve blockade. Apply EMLA cream to intact skin and cover it with an occlusive dressing (e.g., Tegaderm) or apply a transdermal disk. Allow at least 1 hour for the EMLA to take effect. Analgesia is usually satisfactory after 1 hour, peaks at 2 hours, and persists for about 1 hour after it is removed from the skin. The prolonged time required for anesthesia to take effect limits its practical use in the Emergency Department. EMLA should not be applied to infants less than 3 months of age due to the risk of methemoglobinemia.³⁰ The contraindications to using EMLA include allergies to lidocaine or tetracaine and a history of methemoglobinemia.

AMETHOCAINE CREAM

Ametop is another name for the commercial form of amethocaine gel (i.e., 4% amethocaine). It is an alternative to EMLA and is indicated for intact skin. Apply the cream to intact skin and cover with an occlusive dressing. Amethocaine can be used prior to performing lumbar puncture, venous cannulation, minor skin procedures, external auditory canal anesthesia, or regional nerve blockade. It is faster in onset and has greater efficacy than EMLA. Ametop provides adequate anesthesia at approximately 30 to 45 minutes.^{31,32} It works for the pain of intravenous cannulation when compared to

EMLA.³³ Amethocaine decreases the pain of intravenous cannulation and is comparable to 4% liposomal lidocaine.³⁴

LIPOSOMAL AGENTS

Liposomal lidocaine (e.g., LMX-4 or LMX-5) is a 4% or 5% lidocaine cream that is encapsulated in a liposomal matrix. The encapsulation of lidocaine keeps it from being rapidly metabolized. The lipid content of the liposomes allows for better drug penetration of the stratum corneum. The LMX-4 cream has several advantages over other topical anesthetic agents. These include a more rapid onset of action and no requirement for an occlusive dressing. The most frequent adverse reaction is local erythema. No serious side effects have been reported with the use of LMX-4. It is recommended that it be applied for 30 to 60 minutes to an area less than 100 cm² in patients who weigh less than 20 kg.³⁵ Apply the LMX thick and covered with an occlusive dressing. Do not flatten the LMX with the occlusive dressing as it works best when applied thick. Intravenous cannulation after the application of LMX-4 showed improved success rates on the first attempt among children when compared to a placebo.³⁶ A dwell time of 15 minutes was not effective and may be too short.³⁷ The recommended time is 30 to 60 minutes. LMX-4 is as effective as EMLA.³⁸ Buffered lidocaine injection decreased the pain associated with intravenous catheter insertion greater than lidocaine cream.²

TOPICAINE

Topicaïne is a 4% lidocaine gel that is used for procedures in the Emergency Department including placement of Foley catheters and nasogastric tubes. It is readily available and easy to use. Patients can develop a contact dermatitis, particularly if they have an allergy to amide-type local anesthetic agents. Apply Topicaïne for 30 minutes prior to a procedure for maximum efficacy.

ACTIVE NEEDLE-FREE LOCAL ANESTHETIC DELIVERY

An alternative to either the injection of local anesthetic solution or the use of topical creams and gels are needle-free drug delivery systems. These techniques utilize various strategies designed to expedite the delivery of the local anesthetic agent across the stratum corneum. This can reduce wait times to achieve anesthesia from 30 to 60 minutes to within 10 minutes with the use of additional devices (e.g., ultrasound or iontophoresis).³⁹ The clinical utility of these devices is offset by disadvantages including cost of the devices, the bulky equipment, and the limited surface area that can be anesthetized.⁴⁰

ULTRASOUND-ASSISTED LOCAL ANESTHETIC DELIVERY

Ultrasound has been used to accelerate the delivery of topical anesthetic agents (Figure 154-3). Ultrasound disrupts the layers of the stratum corneum, forming temporary pores that facilitate the distribution of topical anesthetic agents below the epidermis.⁴¹ Focal ultrasound followed by a 5 minute application of 4% liposomal lidocaine provided more effective anesthesia when compared to a placebo or standard care.^{42,43} Ultrasound has been shown to reduce the time to achieve anesthesia with EMLA cream from 60 minutes to 5 minutes.⁴⁴ The use of ultrasound prior to a 5 minute application of liposomal lidocaine produced the same amount of pain relief as the typical 30 minute application of liposomal lidocaine.⁴⁵ Ultrasound is effective for intravenous catheter placement and phlebotomy.⁴⁶ It is not associated with the adverse effects of iontophoresis.⁴⁶

IONTOPHORESIS

Iontophoresis is a process by which direct electrical current facilitates dermal penetration of positively charged lidocaine molecules when placed under a positive electrode (Figure 154-2). This allows for enhanced absorption of local anesthesia.⁴⁷ The dose is calculated by multiplying the duration of delivery with the current used to deliver the local anesthetic agent. Studies evaluating this method typically use 20 to 30 mA and 2% lidocaine hydrochloride with 1:100,000 epinephrine.^{48,49} It takes approximately 10 minutes to obtain adequate analgesia for intravenous catheter placement.⁵⁰ The side effects of iontophoresis include skin blanching, erythema, tingling, itching, and burning sensations.⁴⁰ Burns have been reported to rarely occur during iontophoresis with an incidence of 1 per 15,000 to 20,000 treatments.⁵¹ Iontophoresis has been successfully used prior to intravenous catheter placement and lumbar puncture.⁵²

POWDERED ANESTHETICS

Another alternative to the injection of lidocaine solution is the transepithelial injection of powdered lidocaine using a specialized delivery system.⁵³ The delivery system is a prefilled, disposable, single-use device that is designed to produce rapid analgesia for venipuncture and intravenous catheter placement. The system is applied 3 minutes before venipuncture or intravenous cannulation. The device works by releasing pressurized helium, which in turn ruptures a cassette of lidocaine powder. The particles of lidocaine powder are accelerated to a velocity that is sufficient to penetrate the stratum corneum and become deposited in the subepithelial layer. The onset of anesthesia is approximately 1 to 3 minutes after the injection.⁵⁴ This delivery system results in a significant reduction in pain.⁵⁵ The potential adverse effects of powdered lidocaine administration include local skin contusion, application site bleeding, and a subsequent cellulitis.

JET LIDOCAINE

Another form of needle-free lidocaine injection is commonly referred to as jet lidocaine. The device uses pressurized CO₂ to inject up to 0.5 mL of aqueous lidocaine into subcutaneous tissue (Figures 154-5 and 154-9). The lidocaine is drawn up into the reservoir and the device is then held firmly against the skin where the proposed procedure is to occur. The CO₂ cartridge is activated, forcing the micro-aerosolized lidocaine through the stratum corneum and depositing it into the subcutaneous tissues. The local anesthetic travels approximately 5 mm through the skin. The onset of anesthesia is approximately 1 to 3 minutes after the injection. Approximately 20% of patients in a randomized trial experienced pain from administration of the system.⁵⁶ Other complications include device failure 10% of the time and minor local bleeding. It can be used for arterial blood gases, dental anesthesia, facial lacerations, intravenous cannulation, and lumbar punctures.⁵⁷⁻⁵⁹ Jet lidocaine was found to provide more effective anesthesia in studies comparing jet

FIGURE 154-9. Comparison of anesthetic delivery with a needle-free device (left) versus a needle (right). (Photo courtesy of National Medical Products, Orange, CA.)

lidocaine to EMLA or liposomal lidocaine.^{61,62} Jet lidocaine has been found to be more effective than placebo.^{63,64} Jet lidocaine reduced venipuncture pain in pediatric patients when compared to vapocoolant sprays and placebo.⁵⁹ It reduced pain in infants requiring a lumbar puncture when compared to placebo.⁶⁰ One study found jet lidocaine to be no more effective at providing local anesthesia than jet saline.⁶⁵ This suggests that the jet injection itself may play a role in providing anesthesia. The J-tip can cause local anesthetic toxicity.⁶⁶⁻⁶⁸

HEAT-ENHANCED DIFFUSION

The application of heat improves the dermal absorption of topical anesthetics.⁶⁹ The lidocaine-tetracaine topical patch consists of 70 mg of each local anesthesia agent, combined with an air-activated heating system incorporated into an adhesive patch (**Figure 154-6**). It is specifically designed to warm the skin and accelerate the absorption of the local anesthetic agents. The heating component of the patch is automatically activated when the patch is removed from its packaging. It can be used safely in children over the age of 5 months. The only contraindications to using this patch are neonates, allergies to lidocaine, allergies to tetracaine, and a history of methemoglobinemia. The lidocaine-tetracaine patch can be used for minor invasive procedures on intact skin (e.g., lumbar puncture, intravenous catheter placement, and arterial puncture).⁶⁹ The lidocaine-tetracaine patch can provide effective anesthesia after 10 minutes. It was more effective than EMLA or a placebo at all application times shorter than 60 minutes.^{70,71} The patches are just as effective as injection anesthesia for abscess incision and drainage.⁷² Common side effects include skin erythema, blanching, and edema.

LASER-ASSISTED TRANSDERMAL PASSAGE

Another technique to break down the stratum corneum skin barrier involves the use of laser.⁷³ A cutaneous resurfacing laser is used to ablate the outer layer of skin in an area about 6 mm in diameter (**Figure 154-7**). Topical anesthetic is then applied to this area and rapidly penetrates through the ablated skin to the subcutaneous pain receptors. The ablation procedure is typically painless. Anesthesia occurs approximately 5 minutes after the local anesthetic application. The amount of energy used for the ablation varies but typically is in the range of 2.0 to 3.5 J/cm². Side effects may include mild pain, erythema, and itching at the ablation site. The patient may experience temporary hyperpigmentation or hypopigmentation at the treatment site. The biggest drawback to this technique is the cost of the handheld laser.

VAPOCOOLANT SPRAYS

Vapocoolant sprays, also known as vapocoolants and refrigerant sprays, are an alternative to topical local anesthetic agents. Vapocoolant sprays are a good choice for patients requiring brief procedures or with allergies to the medications used in topical anesthetics. Vapocoolant sprays work immediately, are easy to use, are cost effective, and may be repeatedly applied without the risk of methemoglobinemia or systemic toxicity. Vapocoolant sprays are sterile liquids that vaporize upon contact with the skin (**Figure 154-8**). They cool the skin surface as the liquid vaporizes and provide brief topical anesthesia lasting approximately 30 seconds. Commonly used vapocoolants include ethyl chloride, fluorohydrocarbons, and alkane mixtures. Do not use vapocoolants in patients with a known hypersensitivity or allergy to the vapocoolant or its propellant. The topical spray may have antibacterial activity.⁷⁴

Vapocoolants are commercially available in containers with a tip that directs a precise stream of liquid to the desired area

(**Figure 154-8**). The vaporization of the liquid lowers the skin temperature in the area of contact to approximately –20°C (–4°F) as it vaporizes. The skin becomes temporarily cold then frozen. Vapocoolant sprays are convenient, effective, “needle-less,” and provide immediate anesthesia.⁷⁵ Their use is limited by a very brief duration of action of approximately 30 seconds. **These sprays only provide superficial anesthesia and do not traverse the stratum corneum.** Vapocoolant sprays can be used prior to accessing indwelling ports and reservoirs, arterial puncture, venipuncture, intravenous catheter placement, intramuscular injections, local anesthetic injection, lumbar puncture, and minor skin procedures.⁷⁶⁻⁸⁰

Using the vapocoolant spray is very simple. Assemble and gather all the equipment required for the procedure to be performed. Clean and prep the skin. Apply sterile drapes if applicable. Hold the inverted container of refrigerant spray 10 to 15 cm above the skin surface. Spray the liquid onto the skin until a white frost appears and the skin turns white. This usually takes 7 to 12 seconds. Immediately perform the procedure to ensure an adequate anesthetic effect. The area can be surrounded with lubricant to limit skin exposure under the covered areas.

Avoid spraying the liquid onto the skin for prolonged periods as it may result in frostbite, skin hypopigmentation, and atrophic scarring.^{81,82} **Do not use vapocoolant sprays on mucous membranes.** The vapocoolants are significantly absorbed through mucous membranes and can result in adverse reactions and toxicity. These agents are highly volatile and must be used in well-ventilated areas.⁸¹ Neurologic symptoms from inhalation include headache, nausea, vomiting, dizziness, incoordination, disorientation, central nervous system depression, respiratory depression, cardiac arrest, and dysrhythmias from myocardial sensitization to catecholamines.⁸¹ Never spray around open flames or an electrocautery unit as some vapocoolant sprays are highly flammable. Do not use vapocoolant spray on open wounds as it may delay wound healing. Patients were happier with the use of vapocoolant than ice.⁸³ The application of ice packs work, but takes longer to achieve anesthesia.

MUCOUS MEMBRANE ANESTHESIA

Mucous membranes warrant a special note as the systemic absorption from intact mucous membranes is much more rapid and effective than absorption through the skin and results in higher blood levels of the anesthetic agent. Mucous membranes include the nose, mouth, throat, and genitourinary region. Numerous agents may be used to provide anesthesia to mucous membranes (e.g., benzocaine, cocaine, lidocaine, and tetracaine). These local anesthetic agents produce only superficial anesthesia like vapocoolant sprays. They do not provide any pain relief that originates submucosally or deeper. **The total dose applied should be reduced to one-third to one-half the dose used for infiltration to reduce toxicity. Use these agents cautiously on the oral mucosa as they can suppress the gag reflex and increase the risk for aspiration.**

Benzocaine is a commonly used mucous membrane anesthetic for the nose, mouth, and throat. It is available in spray, liquid, and gel form in a concentration of 14% to 20% (e.g., Cetacaine, Hurricaine, Americaine). It is nontoxic when applied to intact mucous membranes due to its poor water solubility. It provides brief analgesia and is often used for tube placement (e.g., nasogastric and orotracheal). **Overuse of benzocaine has the potential to produce methemoglobinemia.**⁸⁴⁻⁸⁶

Cocaine is supplied in solution at concentrations of 4% and 10%. It is an extremely effective mucous membrane anesthetic with significant vasoconstrictive properties which can be helpful in instances such as epistaxis. Systemic absorption is enhanced when it is applied to inflamed mucous membranes. The maximum

dose is 3 mg/kg. This dose still has the potential to result in toxicity and serious complications. **Do not use cocaine in patients with hypertension, cardiomyopathy, or known or suspected coronary artery disease, or patients sensitive to exogenous catecholamines. Cocaine is further limited by its risk of potential abuse.**

Lidocaine is available in jelly and liquid form with a concentration of 2% to 10%. The 2% and 4% viscous solutions are often used in the Emergency Department. Instruct the patient to swish the solution in their mouth for 30 to 60 seconds and then spit it out. It can result in significant systemic absorption if swallowed. The maximal dose is 300 mg in adults (15 mL of 2% or 7.5 mL of 4%) and 3 mg/kg in children. **Use extreme caution when sending patients home with viscous lidocaine for intraoral use.** Frequent use and swallowing can result in elevated blood levels of the parent drug and its metabolites, both of which can result in potential adverse and toxic effects.^{87,88}

Tetracaine is available in liquid and aerosol form with a concentration of 0.25% to 1.0%. It has significant cardiotoxic effects. Therefore, it is not often used for mucous membrane anesthesia. Tetracaine should not be used for mucous membrane anesthesia in the Emergency Department.

MISCELLANEOUS AGENTS

Several alternative topical anesthetic techniques have been used to provide analgesia. These techniques all have the potential to decrease the pain due to procedures. More information and trials are required before these can be used in the Emergency Department.

S-Caine Peel (Zars Pharma) has been developed as a local anesthetic peel. It is composed of 7% lidocaine and 7% tetracaine in an inert base. It is applied to an area for 20 to 30 minutes. It dries into a flexible membrane that can be peeled off after the application period. This agent is easily applied to nonflat body surfaces. Its primary use has been for dermatologic filler procedures, facial laser resurfacing, laser vein treatments, laser tattoo removal, and pulse dye laser treatment.⁸⁹⁻⁹¹ It may be used on intact skin for non-emergent arterial blood gases, intravenous cannulation, and lumbar puncture in the future.

Acupressure has been used for hundreds of years to relieve pain. It has been recently used in acute painful conditions.⁹² It has been successful in reducing or eliminating pain. Most Emergency Physicians are not trained in this modality.

The ShotBlocker (Bionix, Toledo, OH) is a plastic device that is pressed against the skin just before and during an injection.⁹³ It has small bumps on the back that go against the patient's skin. It may be used to decrease the pain of local anesthetic injections. It follows the gate control theory of pain management. The noxious impulses of the ShotBlocker applied to the skin distract from the needle pain.

An anesthetic putty has been developed to relieve pain before laceration repair.⁹⁴ It contains 4.94% lidocaine, which is equivalent to a 4% base solution or 1% injectable lidocaine. The putty is put in the laceration and left to dwell to provide anesthesia. The putty dries as it provides anesthesia. It is removed completely in one mass and does not distort the anatomy. The application and removal are pain-free. This putty is not yet available commercially.

Oral sweet solutions, usually sucrose, have been used for several years for nonemergent procedures.^{8,95-99} These include arterial blood gases, bladder catheterization, heel sticks, intravenous access, and lumbar puncture. The use of these solutions is simple, effective, and easy up to the age of 6 months. It is believed they work through distraction and the release of endogenous opioids. Apply 1 mL in each cheek or allow sucking from a pacifier just before the procedure. The only contraindications are suspected or actual necrotizing enterocolitis and postoperative abdominal surgery. One study in children 1 to 3 months of age showed sweet solutions did not decrease pain

scores or heart rates but did decrease the crying time.¹⁰⁰ There is no real downside for trying sweet solutions to reduce pain.

ASSESSMENT

Wait long enough after the topical agent is administered to allow the onset of adequate anesthesia before the planned procedure is started. The time necessary for the onset of anesthesia is highly variable and dependent on the topical anesthetic used and the delivery technique utilized. A simple examination of the area being anesthetized with fine touch and pinprick ensures adequate anesthesia prior to the procedure. It may be necessary to apply additional anesthetic or use an alternative anesthetic technique in areas of continued sensitivity, keeping in mind the total dose applied to avoid toxicity.

AFTERCARE

Observe the patient for a minimum of 15 minutes following the use of topical anesthesia to ensure no evidence of an adverse reaction or toxicity. The patient need not wait in the Emergency Department for normal sensation to return prior to discharge.

COMPLICATIONS

The use of topical and noninvasive anesthesia occasionally causes adverse effects. There are case reports of patients developing central nervous system toxicity after the application of topical anesthetics.¹⁰¹ There have been cases of methemoglobinemia reported in patients, particularly with the use of benzocaine.⁸⁴ Topical anesthetics in patients taking class I antiarrhythmics (e.g., mexiletine and tocainide) can produce additive and possibly toxic effects. EMLA has been reported to cause ulceration of the gingival mucosa and should not be used for mucosal anesthesia.¹⁰² Many of the topical anesthetics are contraindicated or require special ophthalmic formulations for use in the eye. Special care and attention to dosing are imperative to avoid toxicity. This is especially true when using topical anesthetics in neonatal patients

SUMMARY

There are effective techniques available to decrease the pain and anxiety associated with invasive procedures. Topical and noninvasive anesthetic agents, particularly those with fast-acting properties, are excellent adjuncts for use in the Emergency Department. Topical creams, active medication delivery, or alternative techniques should be considered prior to performing a painful invasive procedure.

Hematoma Blocks

Thomas P. Graham

INTRODUCTION

Distal extremity fractures are commonly seen in the Emergency Department. These fractures often require closed reduction by manipulation which can be a painful and frightening experience for the patient. Achieving adequate analgesia is important to

facilitate reduction and to minimize patient discomfort. Physicians frequently provide inadequate analgesia to patients, and particularly children, with extremity fractures.^{1,2}

ANATOMY AND PATHOPHYSIOLOGY

The hematoma block is a technique to inject a local anesthetic solution into the hematoma between the fractured bone fragments. Fracture manipulation can often be undertaken painlessly or with significantly reduced pain after performing a hematoma block. Hematoma blocks of the distal forearm are considered safe in children and adults.³⁻⁸ A hematoma block may be superior to intravenous sedation in alleviating discomfort during fracture reduction.⁹ Other advantages are the relative ease of the procedure, no worries concerning aspiration, and ability to potentially manage the airway. The hematoma block avoids the side effects of sedating drugs, does not require intravenous access and cardiac monitoring, and is not associated with a prolonged recovery phase. The Emergency Physician can safely perform a hematoma block alone whereas two health care providers are needed for procedural sedation. The disadvantages of the hematoma block include the discomfort and anxiety resulting from injecting into the fracture site. There is the potential for a rare complication.

Extremity fractures that are displaced or angulated result in the formation of a hematoma between the fracture fragments. The hematoma is easily accessible with a needle. The injection of local anesthetic solution can significantly alleviate pain. Most important neurovascular structures in the upper extremity are contained in the volar soft tissue, making the dorsal or lateral approach preferred. Most important neurovascular structures in the lower extremity are contained in the proximal anterior thigh or posteriorly in the leg, making the lateral approach preferred in the proximal thigh and the anterior or lateral approach from the mid-thigh distally.

Other techniques are available to provide analgesia and anesthesia. A Bier block (Chapter 157) may lead to more effective anesthesia and require fewer repeat manipulations for the reduction of forearm fractures when compared to the hematoma block.¹⁰⁻¹² The Bier block is a technique with which most Emergency Physicians are not familiar and have not developed proficiency. It often requires equipment not commonly available in the Emergency Department and can be associated with adverse outcomes. Intraarticular injection of local anesthetic solution for the reduction of intraarticular fracture-dislocations has been advocated as safe and effective.^{13,14} The joints of the extremities are easily entered by performing an arthrocentesis (Chapter 97). Local anesthetic solution injected intraarticularly diffuses throughout the joint cavity and exits through the fracture site to alleviate pain.

INDICATIONS

A hematoma block is indicated in adult and pediatric patients with closed fractures of the extremity that require manipulation or closed reduction.¹⁵⁻¹⁸ Consider performing a hematoma block when medical resources are limited or scarce. It is an alternative when procedural sedation is impossible or impractical.^{15,17,19} A hematoma block may be performed purely for analgesia when fracture manipulation is unnecessary and/or other methods of analgesia are ineffective or contraindicated.

CONTRAINDICATIONS

Hematoma blocks are contraindicated when there is a history of allergic reactions to local anesthetic agents. The procedure is contraindicated in the setting of an open fracture, cellulitis overlying the fracture site, the presence of a neurovascular deficit, or the

presence of a vascular deficit. Do not perform a hematoma block if a sterile field cannot be maintained or the safety of the medical staff cannot be assured due to an uncooperative patient. Relative contraindications include patients with bleeding disorders and those taking anticoagulants. The potential additional hemorrhage from the injection of local anesthetic solution into a closed space may result in a compartment syndrome (Chapters 93 and 94).

EQUIPMENT

- Sterile gloves and gown
- Face mask and cap
- Povidone iodine or chlorhexidine solution
- Sterile drapes
- Lidocaine (i.e., 1% or 2%) or bupivacaine (i.e., 0.25% or 0.5%), without epinephrine
- Syringes, various sizes
- 22 or 23 gauge, 2 inch long needles
- Spinal needles for obese patients

OPTIONAL EQUIPMENT

- Ultrasound machine
- 7.5 to 10 MHz ultrasound transducer
- Sterile ultrasound gel
- Sterile ultrasound transducer cover

PATIENT PREPARATION

Explain the risks, benefits, complications, and alternatives to the patient and/or their representative. The technique for adult and pediatric patients is identical. An adult usually tolerates the hematoma block injection without any supplemental analgesia or sedation. Some adults and children may require supplemental nitrous oxide (Chapter 158), intravenous sedation (Chapter 159), or an intravenous anxiolytic agent to facilitate the hematoma block.

Prepare for the procedure. **The hematoma block must be performed using aseptic technique.** Cleanse the skin of any dirt and debris over the fracture site and surrounding skin. Apply povidone iodine or chlorhexidine solution onto the skin and allow it to dry. Apply sterile drapes to delineate a sterile field. Don sterile gloves, a sterile gown, a face mask, and a cap during the procedure. Use sterile technique and draw up the local anesthetic solution into a syringe armed with a 22 or 23 gauge, 2 inch long needle. Bupivacaine can be used by itself or mixed with lidocaine in a 50-50 ratio if postprocedure analgesia is desired. A longer spinal needle may be required to reach the fracture in the obese patient. Fill the syringe to a maximum of 10 mL of local anesthetic agent to be injected. Larger volumes may be required in adults and with larger fractures. Always be aware of the maximum safe dose of lidocaine or bupivacaine (Chapter 153).

TECHNIQUES

LANDMARK (BLIND) HEMATOMA BLOCK

Follow strict sterile technique throughout the procedure. Inform the patient of the early signs of local anesthetic toxicity. These include circumoral and tongue numbness, dizziness, lightheadedness, mental status decline, tinnitus, and visual disturbances. Instruct the patient to inform you immediately if they experience any of these symptoms.

FIGURE 155-1. Schematic illustration of the hematoma block.

Place a wheal of 1% lidocaine subcutaneously over the fracture site. Allow 1 to 2 minutes for the anesthetic to take effect. Slowly insert and advance the 23 gauge needle attached to the local anesthetic solution in the syringe. Insert the needle through the skin wheal and aimed at the fracture site. Continue to slowly advance the needle toward and into the expected location of the gap between the fracture fragments (**Figures 155-1 and 155-2**). **Aspirate with the syringe to ensure there is no free flow of blood. This indicates the tip of the needle is within a blood vessel. Do not inject the local anesthetic solution.**^{20,21} A flash of blood indicates entry of the tip of the needle into the hematoma. Withdraw the needle and redirect it to enter the hematoma if the needle strikes bone or if no flash of blood is returned. Slowly inject the local anesthetic solution into the hematoma. Withdraw the needle. Apply a bandage to the skin puncture site.

Some will reposition the needle to different areas within the hematoma and inject small amounts of the local anesthetic solution into each area (**Figure 155-2B**). This technique distributes the local anesthetic solution to increase the efficacy of the hematoma block. Injection into multiple areas also minimizes the risk of intravascular injection of the entire dose of local anesthetic solution.

HEMATOMA BLOCK FOR INTRAARTICULAR FRACTURE-DISLOCATIONS

The procedure is identical to that described above except for the anatomic landmarks and the volume of local anesthetic solution injected. Refer to Chapter 97 for the complete details of an arthrocentesis.

ULTRASOUND-GUIDED HEMATOMA BLOCK

The use of ultrasound (US) can facilitate the injection into the correct site.¹²⁻²⁷ Identify the fracture site and hematoma using US. Place the US transducer on the patient's skin above the fracture site. Turn the US transducer so its long axis is aligned with the long axis of the bone. Identify the fracture site and hematoma. Rotate the US transducer 90° to visualize the short axis or cross-sectional view of the fracture site and hematoma.

Clean, prep, and sterilely drape the patient as described previously. Inject local anesthetic solution subcutaneously over the fracture site. Prepare the US transducer. Apply US gel to the footprint of the US transducer. Apply a sterile transducer cover or a sterile glove over the US transducer. Squeeze any air out of the space between the US transducer and the cover. Apply sterile US gel on the transducer cover.

Grasp the sterile US transducer with the nondominant hand. Align the long axis of the US transducer along the long axis of the bone and approximately 8 to 10 mm proximal to the fracture site. Aim the syringe containing the local anesthetic solution downward and in the direction of the fracture site. Slowly insert and advance the needle through the skin under US guidance. Advance the needle

into the hematoma at the fracture site (**Figure 155-3**). Inject the local anesthetic solution. Remove the needle and apply a bandage to the skin puncture site.

ALTERNATIVE TECHNIQUES

Several adjuncts to the hematoma block may aid in increasing its efficacy. The addition of hyaluronidase to the local anesthetic solution has been advocated at some centers as a means of increasing the speed and efficiency of the hematoma block. The hyaluronidase breaks down the connective tissue and allows better penetration of the local anesthetic solution into the area. The evidence for the efficacy of hyaluronidase is currently lacking.²⁸ **It is not currently recommended to add hyaluronidase to the local anesthetic solution.** Some authors recommend the use of other agents (e.g., anxiolytics) in combination with the hematoma block for fracture manipulation. Combining the hematoma block with nitrous oxide has shown positive results.²⁹

ASSESSMENT

Reassess and document a thorough neurologic and vascular examination distal to the fracture site immediately after the injection. Assess the patient's level of pain with gentle range of motion in

10 minutes. A second injection of local anesthetic solution may be performed if required for analgesia if the patient is not experiencing any side effects or toxicity and the total combined doses do not exceed the maximum allowable limit.

AFTERCARE

The extremity can be manipulated to reduce the fracture once adequate analgesia has been obtained. Splint the extremity. **Perform and document another neurologic and vascular examination of the extremity after any manipulation and splinting.** Instruct the patient to immediately return to the Emergency Department for severe pain, significant swelling, numbness, paresthesias, or pallor of the extremity. Arrange appropriate follow-up with an Orthopedic Surgeon. Prescribe analgesics as appropriate.

COMPLICATIONS

The complications associated with a hematoma block are rare.¹⁵ These include a compartment syndrome, local anesthetic toxicity, and osteomyelitis.³⁰⁻³⁶ The early signs of local anesthetic toxicity include circumoral and tongue numbness, dizziness, lightheadedness, mental status decline, tinnitus, and visual disturbances. The cardiovascular toxic effects include asystole, atrioventricular blocks, bradycardia, cardiac depression, dysrhythmias, and hypotension. The neurologic toxic effects include agitation, coma, confusion, headaches, seizures, and possibly death.^{21,37} Seizures associated with local anesthetic toxicity are usually short lasting and respond to barbiturates, benzodiazepines, and propofol. Refer to Chapters 153, 154, and 157 for the complete details regarding local anesthetic complications and toxicity. Introducing bacteria into a previously closed fracture and injury to vascular structures are potential complications. These can be minimized or eliminated by using strict sterile technique and carefully identifying the anatomic landmarks.

SUMMARY

A hematoma block is an effective technique to facilitate manipulation of extremity fractures and intraarticular fracture-dislocations in adults and children. It may be performed purely for analgesia when no manipulation is required. Complications are rare if proper techniques are used. The procedure requires fewer Emergency Department resources than procedural sedation or a Bier block. Consider performing a hematoma block when procedural sedation is impractical or contraindicated. Consider patient preference. Most patients would prefer a shorter Emergency Department stay with a hematoma block rather than a much longer one involving procedural sedation and the associated risks.

Regional Nerve Blocks (Regional Anesthesia)

Eric F. Reichman and Jehangir Meer

INTRODUCTION

Regional anesthesia or regional nerve blocks are defined as infiltration of a peripheral nerve with local anesthetic agents to attenuate motor output and sensory input. It provides anesthesia to allow problems to be treated efficiently and with minimal discomfort. Patients typically tolerate nerve blocks better than direct wound infiltration. Nerve blocks often require less local anesthetic solution than does infiltration of large wounds.

Regional anesthesia provides sensory blockade of a region without altering the normal anatomic features of the area to be repaired.¹ It may be considered for use in the repair of extensive wounds, incision and drainage of abscesses, foreign body removal, wound exploration, burn care, fracture reduction, or pain control. Once familiar with the body's sensory innervation, the Emergency Physician can easily employ regional anesthesia techniques within the Emergency Department.

Locating and anesthetizing a peripheral nerve is accomplished in one of four ways. First is to identify the general location of the nerve using anatomy and landmarks. Infiltrate local anesthetic solution at that site and allow it to diffuse over the area. The second is to locate a nerve by using the injecting needle to elicit paresthesias. Once paresthesias are elicited, withdraw the needle 1 to 2 mm and allow the paresthesias to resolve before injecting the local anesthetic solution. Third, a nerve stimulator can be used to accurately locate peripheral nerves with motor fiber components. Use of a nerve stimulator does not require cooperation on the part of the patient. However, due to its complexity, a physician skilled in its use is required. Nerve stimulators are rarely available in the Emergency Department. Finally, ultrasound can be used to identify the target nerve and to inject the local anesthetic solution.

The traditional method used by Anesthesiologists to perform regional anesthesia involves a combination of surface landmarks and nerve stimulation. Over the past 10 to 15 years, ultrasound (US) has gained a prominent role in guiding nerve blocks. It offers the advantages of visualizing the nerve and the needle, as well as directly visualizing the deposition of local anesthetic solution around the nerve. Several small initial studies have shown that Emergency Physicians can safely perform US-guided nerve blocks.²⁻⁵

It is common to encounter children complaining of pain in the Emergency Department. Regional anesthesia is frequently overlooked in children. Its use is increasing and serves as an excellent opportunity to minimize pain in the pediatric population.⁶ It can be administered safely and effectively in these patients. A child may require intravenous or intramuscular sedation in conjunction with nerve blockade in more complicated cases. The use of nitrous oxide with pediatric patients in the Emergency Department has been found to be successful when used for forearm fracture manipulation.⁷ It can also be used for other procedures. Refer to Chapter 158 regarding the use of nitrous oxide as a supplement to performing the regional nerve block. The disadvantages of performing regional nerve blocks in children include the extra time required to perform the block, mandatory technical dexterity, and assistant support because the child may not remain still for the procedure.

This chapter covers the commonly performed Emergency Department regional anesthetic blocks of the head, neck, upper extremity, lower extremity, and two of the many torso blocks (**Table 156-1**). Dental blocks are discussed in Chapter 209. Refer to Chapter 153 for a more complete discussion on the properties of local anesthetic agents.

TABLE 156-1 Nerves and Anatomic Areas That Can Be Anesthetized in the Emergency Department Using a Regional Block

Head and neck	Lower extremity	Upper extremity	Torso
Supraorbital nerve block	Femoral nerve block	Brachial plexus block	Intercostal block
Supratrochlear nerve block	Saphenous nerve block	Median nerve block	Penile nerve block
Infraorbital nerve block	Lateral femoral cutaneous nerve block	Ulnar nerve block	
Mental nerve block	Obturator nerve block	Radial nerve block	
Greater occipital nerve block	Sciatic nerve block	Wrist block	
Lesser occipital nerve block	Popliteal fossa block	Digital nerve block	
Greater auricular nerve block	Common peroneal nerve block		
Scalp block	Superficial peroneal nerve block		
External ear block	Deep peroneal nerve block		
External auditory canal block	Sural nerve block		
Cervical plexus block	Posterior tibial nerve block		
	Ankle block		
	Digital nerve block		

ANATOMY AND PATHOPHYSIOLOGY

There is a topographic arrangement of axons within peripheral nerves (**Figure 156-1A**).^{8,9} Axons located in the outer or mantle layer innervate proximal structures. Axons in the center of the nerve or core layer innervate distal structures. Local anesthetic solution injected near a nerve diffuses from the mantle layer to the core layers. **This explains why anesthesia slowly spreads along the nerve distribution in a proximal to distal direction.**

Avoid intraneural injection when performing peripheral nerve blocks. The nerve has a tough, fibrous outer sheath that acts as a physical barrier to trap intraneural fluid (**Figure 156-1B**). Injection of local anesthetic agents into the nerve bundle will compress the fragile axons and their capillary blood supply.^{10,11} This can result in axonal necrosis and permanent nerve damage. **Paresthesias elicited upon needle insertion indicate that the tip of the needle is within the nerve bundle. Withdraw the needle 1 to 2 mm and allow the paresthesias to resolve, usually within 15 to 30 seconds. The anesthetic agent can be safely injected when the paresthesias resolve.**

Cutaneous innervation is referenced to a segment known as a dermatome.⁸ This is defined as an area of skin supplied by a single spinal or segmental nerve. This type of innervation is best represented in worms where each body segment has its own nervous supply. The pattern of segmental innervation still holds true with some minor modifications as one moves up the phylogenetic tree. The truncal dermatomes in humans are represented as simple bands while the extremity dermatomes are serpiginous and follow the embryonic rotation of the limb buds. The most commonly used dermatomal chart is that developed by Keegan and Garrett (**Figure 156-2**).⁹ Their model of the extremity dermatomes is in strips of innervation, all originating from the limb base and extending distally. This system is used in clinical medicine today.

INDICATIONS

Regional anesthesia produces profound analgesia with minimal physiologic or anatomic alteration. These techniques are especially useful in large or extensive lacerations that would otherwise require the infiltration of a large and potentially toxic volume of

FIGURE 156-1. The anatomy and topographic arrangement of axons in a peripheral nerve. **A.** The gross anatomy of a peripheral nerve. **B.** The microscopic anatomy of a peripheral nerve.

FIGURE 156-2. The dermatomal chart of the human body.

local anesthetic solution. Nerve blocks can avoid a patient being taken to the Operating Room because the volume of local anesthetic required for extensive wound repair may require toxic doses. These techniques are also useful in cosmetic repairs where local infiltration may cause distortion of tissues or loss of anatomic landmarks making approximation and repair difficult. The necessity to palpate deep tissue for excision is also an indication for regional anesthesia.^{12,13} Regional nerve blocks can be performed prior to burn care, dislocation or fracture reduction, foreign body removal, incision and drainage of abscesses, pain control, wound exploration, and wound care.

US-guided regional anesthesia offers a number of advantages when compared with the anatomic landmark. It is safer and results in fewer complications (e.g., vascular puncture, pneumothorax, intravascular injection of local anesthetic).¹⁴ US achieves higher rates, over 95%, of successful blocks and delivers a more rapid onset of anesthesia. In addition, a smaller volume of local anesthetic solution is required for the block.¹⁴ US can eliminate the need for procedural sedation and analgesia (PSA) and its potential complications (e.g., apnea, hypoxia, and hypotension). Preprocedural fasting is not required as it is a potential requirement in PSA. US-guided nerve blocks reduce Emergency Department lengths of stay compared

with patients receiving PSA.² It facilitates procedures in patients with higher American Society of Anesthesiology (ASA) classification scores who would otherwise be put at higher risk for complications by the administration of PSA.

CONTRAINDICATIONS

There are few contraindications to regional anesthesia.^{8,15,16} Absolute contraindications include injection through infected tissue, history of a bleeding disorder or a coagulopathy, or an allergy to the anesthetic agent. **Relative contraindications include preexisting neurologic damage prior to the procedure. This should carefully be documented before any anesthetic injection.** Patients with altered mental status or the inability to cooperate (e.g., developmental delay, intoxication, or young children) should have an alternative treatment plan instead of a regional nerve block.^{6,17,18} They would not be able to provide the feedback of paresthesias in case of intra-neural needle placement.

There are no patient contraindications to the use of US to guide nerve blocks. Emergency Physician contraindications include the lack of familiarity and training with the procedure. Psychomotor

TABLE 156-2 Maximum Doses of Local Anesthetic Agents

Anesthetic agent	Maximum dose (mg/kg)	Duration of action (min)
Procaine (2%)	6	15–30
Procaine (2%) with epinephrine	8	30–90
Tetracaine (0.25%)	1	120–140
Tetracaine (0.25%) with epinephrine	2	240–280
Chlorprocaine (2%)	8	15–30
Chlorprocaine (2%) with epinephrine	10	30–90
Lidocaine (1%)	3	30–120
Lidocaine (1%) with epinephrine	5	60–400
Etidocaine (0.5%)	3	30–120
Etidocaine (0.5%) with epinephrine	4	60–200
Mepivacaine (1%)	3	30–120
Mepivacaine (1%) with epinephrine	5	60–400
Bupivacaine (0.25%)	1.75	120–240
Bupivacaine (0.25%) with epinephrine	2.25	240–480
Prilocaine (4%)	5	30–60
Prilocaine (4%) with epinephrine	6	120–300

coordination and experience with US are required. Caution is advised for the novice ultrasonographer.

EQUIPMENT

■ ANATOMIC LANDMARK-GUIDED NERVE BLOCKS

- Sterile gloves
- Sterile drapes
- Povidone iodine or chlorhexidine solution
- Alcohol swabs
- Local anesthetic solution (Table 156-2 and Chapter 153)
- 18 gauge needle to draw up local anesthetic solution
- 20 to 27 gauge noncutting or Quincke needles for injection, 2 inches long
- 22 to 24 gauge noncutting or Quincke spinal needles
- 1, 3, 5, 10, and 60 mL syringes
- Intravenous extension tubing

■ US-GUIDED NERVE BLOCKS

- Above listed supplies
- US machine
- High-frequency, linear-array, US transducer
- Sterile US transducer cover
- Sterile US gel
- Noncutting needles

All of the required equipment is readily available in any Emergency Department. Some have a preprepared tray or tackle box containing all the required equipment.

Numerous additives are used to supplement the local anesthesia agent injected for regional anesthesia.¹⁹ The authors do not recommend their use in the Emergency Department. The additives can have numerous side effects and have not been studied for their use outside of the anesthesia literature.

PATIENT PREPARATION

Explain the procedure, its risks, and benefits to the patient and/or their representative. Emphasize that there are few complications with this procedure. However, all possible complications should

be discussed beforehand. Inform the patient of the possibility of paresthesias during the procedure and of the expected duration of action of the local anesthetic agent (Table 156-2). **Obtain an informed consent for the regional nerve block in addition to the procedure for which it is performed.** Ideally, the consent should be documented in the medical record and signed by the patient. Some Emergency Physicians prefer to note on the patient's chart "indications, risks, and benefits were discussed with the patient" rather than having the patient sign a consent form. This decision is specific to each Emergency Physician, their institution, and state requirements.

Perform and document a neurologic examination of the area to be anesthetized before performing regional anesthesia. Include a description of any neurologic deficit in the document of informed consent for the procedure. Have the patient sign an agreement that the defect was present prior to the administration of the local anesthetic solution.

Position the patient based upon the specific regional block to be performed. Place the patient supine on a gurney or procedure table prior to the procedure in most cases. If the patient must sit upright, place the patient on an adjustable bed. The patient's comfort should be optimized to prevent unexpected complications such as vasovagal syncope.^{8,20,21} Expose the area of the injection and identify the anatomic landmarks required for proper needle placement. Clean all dirt and debris from the skin. Scrub the needle insertion site with povidone iodine or chlorhexidine solution and allow it to dry. Apply sterile drapes to delineate a sterile field.

If using US guidance, prepare the US transducer. **Always use a sterile US transducer cover and sterile US gel when performing nerve blocks to prevent deep infections.** Set up a sterile field on a bedside table. Open the US transducer cover set onto the sterile field. Instruct an assistant to hold the US transducer upright and place standard or sterile US gel on the footprint of the US transducer (Figure 63-6A). Apply the sterile transducer cover over the US transducer (Figure 63-6B). Smooth all the air bubbles away from the footprint of the US transducer to prevent imaging artifacts. Secure the cover with rubber bands to prevent it from sliding off the US transducer (Figure 63-6C). Place the US transducer on the sterile field (Figure 63-6D). Apply sterile US gel onto the cover over the US transducer footprint just before scanning.

TECHNIQUE

The general procedure will first be described and specifics will be addressed with each individual nerve block.

ANATOMIC LANDMARK TECHNIQUE

Position the patient. Identify the nerve or nerves to be blocked and their associated anatomic landmarks. Carefully clean and prepare the skin over the injection site in a sterile fashion. Draw up the local anesthetic solution to be injected. The amount will vary based on the specific block. Always keep in mind the maximum allowable dose of local anesthetic (Table 156-2). Reidentify the anatomic landmarks. Insert the needle into the site. Withdraw the plunger to ensure that the tip of the needle is not within a blood vessel, thus avoiding intravascular injection. If paresthesias are elicited, withdraw the needle 1 to 2 mm and allow them to resolve. Inject the local anesthetic solution. Apply an appropriate bandage to the site. Allow 5 to 15 minutes for the block to take effect. Confirm that anesthesia has been achieved with pinprick prior to performing the procedure for which regional anesthesia was performed. Document the regional anesthesia procedure, the procedure for which regional anesthesia was performed, and any complications in the medical record. A sample regional anesthesia procedure note is provided in Table 156-3.

TABLE 156-3 A Sample Regional Anesthesia Procedure Note

After informed consent and identification of the necessary landmarks, the skin overlying _____ (location) was cleaned and prepped with povidone iodine or chlorhexidine solution. Using sterile technique, a skin wheal of local anesthetic solution was placed. A _____ gauge needle was used to anesthetize the _____ nerve with _____ mL of _____ % _____ (lidocaine, marcaine, procaine, etc.). Anesthesia was confirmed with needle pinprick testing. No complications were noted.

ULTRASOUND-GUIDED TECHNIQUE

Position and prepare the patient as described above for the anatomic landmark technique. Find the general location of the nerve using anatomic landmarks. Use US to identify the targeted nerve. Use the nondominant hand to hold the US transducer. Manipulate the needle with the other hand. Center the target nerve on the monitor screen.

Use a longitudinal or in-plane needle approach for all US-guided nerve blocks. The US transducer should image the nerve bundle in the short axis, allowing the entire length of the needle to be visualized as it approaches the nerve. Use a noncutting needle, such as a Quincke spinal needle, to reduce the risk of intraneural injection or nerve injury. Place the US machine on the patient's opposite side to allow the Emergency Physician to glance easily and quickly from the field to the US monitor. Connect a short IV extension tubing to allow easier manipulation of the needle if an assistant is available. The assistant can hold the syringe containing the local anesthetic and inject it under the direction of the Emergency Physician who is controlling the needle. An extra level of safety for the novice performing this injection is to have the supervising physician control the syringe and injection.

An important concept regarding the injection of local anesthetic solution around the nerve bundle is the "donut sign." This is the circumferential spread of local anesthetic solution around the nerve. This is the desired location of the local anesthetic solution around the nerve and it is usually associated with a successful block.

REGIONAL ANESTHESIA TECHNIQUES FOR THE HEAD AND NECK

SUPRAORBITAL NERVE BLOCK

Anatomy: The supraorbital foramen lies on the supraorbital ridge along a line drawn through the pupil in the midposition (Figures 156-3 and 156-4). The supraorbital foramen may be palpable as an indentation. The supraorbital nerve is a branch of the ophthalmic division of the trigeminal nerve. It emerges through the supraorbital foramen, or notch, at the midline of the superior orbital ridge (Figure 156-4A). Its area of innervation includes the forehead beginning at the superior orbital ridge and extending superiorly to the vertex of the scalp. It is blocked simultaneously with the supratrochlear nerve as there is considerable overlap in their areas of innervation.

Patient positioning: Place the patient supine, or sitting, and facing the Emergency Physician.

Landmarks: Identify, under the eyebrow, the superior orbital rim and the supraorbital foramen by palpation.

Needle insertion and direction: Place a skin wheal of local anesthetic solution over the midline of the forehead at the level of the eyebrow. Insert a 25 or 27 gauge needle through the skin wheal and aimed laterally (Figure 156-4B). Advance the needle while infiltrating subcutaneously with 3 to 5 mL of local anesthetic solution. Always maintain the needle just above the supraorbital ridge while advancing it (Figure 156-4B). Stop infiltrating when the needle passes the midline of the bony orbit.

FIGURE 156-3. The supraorbital foramen, the infraorbital foramen, and the mental foramen all lie along a straight line drawn through the pupil in the midposition.

US-guided block: The nerve can also be located exiting the foramen with US. Find the foramen where the nerve exits with US. Inject 1.5 mL of the local anesthetic just outside the foramen. **Do not inject into the foramen as this can put pressure on the nerve and result in necrosis.**

Remarks: This technique will anesthetize both the supraorbital and supratrochlear nerves. Infiltrate 2 mL of local anesthetic solution directly over the supraorbital foramen or notch, if it is palpable, rather than subcutaneously infiltrating above the supraorbital ridge.

SUPRATROCHLEAR NERVE BLOCK

Anatomy: The supratrochlear nerve is a branch of the ophthalmic division of the trigeminal nerve. It emerges through the trochlea at the superomedial aspect of the bony orbit (Figure 156-4A). It provides innervation to the middle of the forehead beginning at the superior orbital ridge and extending superiorly to the vertex of the scalp. It is often blocked simultaneously with the supraorbital nerve as there is considerable overlap in their areas of innervation.

Patient positioning: Place the patient supine, or sitting, and facing the Emergency Physician.

FIGURE 156-4. The supraorbital and supratrochlear nerve block. **A.** The location of the nerves. **B.** Insertion of the needle.

Landmarks: Identify, under the eyebrow, the superior orbital rim by palpation.

Needle insertion and direction: Place a skin wheal of local anesthetic solution over the midline of the forehead at the level of the eyebrows. Insert a 25 or 27 gauge needle through the skin wheal, aimed laterally (Figure 156-4B). Advance the needle while infiltrating subcutaneously with 2 to 3 mL of local anesthetic solution. Always maintain the needle just above the supraorbital ridge while advancing it (Figure 156-4B). Stop infiltrating when the needle passes the midline of the bony orbit.

Remarks: Stop infiltrating 1.5 cm from the skin wheal so as to block only the supratrochlear nerve.

INFRAORBITAL NERVE BLOCK, EXTRAORAL APPROACH

Anatomy: The infraorbital nerve is a branch of the maxillary division of the trigeminal nerve. It emerges through the infraorbital foramen 1 cm below the middle to medial third of the inferior orbital ridge (Figure 156-5A). It lies in the same plane as the supraorbital foramen and pupil that is in the midposition (Figures 156-3 and 156-5). The nerve exits the infraorbital foramen and travels inferiorly and medially. It provides sensory innervation to the medial cheek, nasal ala, upper lip, and skin between the upper lip and nose. The infraorbital nerve terminates as the anterior and middle superior alveolar nerves. They provide sensory innervation to the maxillary incisors, canine, and premolar teeth, as well as their bony support and surrounding soft tissues.

Patient positioning: Place the patient supine, or sitting, and facing the Emergency Physician.

Landmarks: Identify the infraorbital foramen by palpation. Significant tenderness will be elicited when the infraorbital nerve is palpated as it exits the infraorbital foramen.

Needle insertion and direction: Insert a 25 or 27 gauge needle just above the infraorbital foramen (Figure 156-5B). Advance the needle until the maxilla is contacted. Inject 1 to 2 mL of local anesthetic solution.

US-guided block: The nerve can also be located exiting the foramen with US. Find the foramen where the nerve exits with US. Inject 1.5 mL of the local anesthetic just outside the foramen. **Do not inject into the foramen as this can put pressure on the nerve and result in necrosis.**

Remarks: The infraorbital nerve can be blocked intraorally. The intraoral route results in the patient experiencing less pain than the extraoral route.

FIGURE 156-5. The extraoral approach to the infraorbital nerve block. **A.** Location of the nerve. **B.** Insertion of the needle.

FIGURE 156-6. The intraoral approach to the infraorbital nerve block. **A.** Location of the nerve. **B.** Insertion of the needle.

INFRAORBITAL NERVE BLOCK, INTRAORAL APPROACH

Anatomy: The anatomy and innervation of the infraorbital nerve is described in the previous section.

Patient positioning: Place the patient supine, or sitting, and facing the Emergency Physician.

Landmarks: Identify the infraorbital foramen by palpation. It lies in a plane with the supraorbital foramen and the pupil in the midposition (Figures 156-3 and 156-6A).

Needle insertion and direction: Place the index finger of the nondominant hand over the infraorbital foramen (Figure 156-6B). Use the nondominant thumb to retract the upper lip. Insert a 2.5 to 4.0 cm, 25 or 27 gauge needle through the mucous membranes and directed toward the index finger. Advance the needle until its tip is palpable at the infraorbital foramen by the index finger. The estimated depth of needle penetration is 1.0 to 1.5 cm. Inject 2 mL of local anesthetic solution.

US-guided block: The nerve can also be located exiting the foramen with US. Find the foramen where the nerve exits with US. Aim and advance the needle toward the US transducer. Inject 1.5 mL of the local anesthetic just outside the foramen. **Do not inject into the foramen as this can put pressure on the nerve and result in necrosis.**

Remarks: This is the preferred route to block the infraorbital nerve. It can also be blocked extraorally.

MENTAL NERVE BLOCK, EXTRAORAL APPROACH

Anatomy: The mental nerve is a branch of the mandibular division of the trigeminal nerve. It emerges from the mental foramen. The foramen lies in a vertical plane with the supraorbital foramen, the infraorbital foramen, and the pupil that is midposition (Figures 156-3 and 156-7). The nerve travels inferiorly and anteriorly to provide sensory innervation to the skin of the lower lip and chin.

Patient positioning: Place the patient supine, or sitting, and facing the Emergency Physician.

Landmarks: Identify the vertical plane consisting of the supraorbital foramen, the infraorbital foramen, and the midposition pupil (Figure 156-3). Identify the point where the vertical plane crosses the middle of the body of the mandible (Figure 156-7A). This is where the mental nerve exits the mental foramen.

Needle insertion and direction: Insert a 25 or 27 gauge needle at the above identified landmark (Figure 156-7B). Place a skin wheal

FIGURE 156-7. The extraoral approach to the mental nerve block. **A.** Location of the nerve. **B.** Insertion of the needle.

of local anesthetic solution at this intersection. Advance the needle through the skin wheal until the mandible is contacted. Inject 1 to 2 mL of local anesthetic solution.

US-guided block: The nerve can also be located exiting the foramen with US. Find the foramen where the nerve exits with US. Inject 1.5 mL of the local anesthetic just outside the foramen. **Do not inject into the foramen as this can put pressure on the nerve and result in necrosis.**

Remarks: This nerve can also be blocked intraorally. The intraoral route results in the patient experiencing less pain than the extraoral route.

MENTAL NERVE BLOCK, INTRAORAL APPROACH

Anatomy: The anatomy and innervation of the mental nerve are described in the previous section.

Patient positioning: Place the patient supine, or sitting, and facing the Emergency Physician.

Landmarks: Retract the lower lip and identify the junction of the first and second premolars. The patient's mouth may be open or closed.

Needle insertion and direction: Insert a 25 or 27 gauge needle directed inferiorly and posteriorly through the gingival mucosa at the junction of the first and second premolars (**Figure 156-8**).

FIGURE 156-8. The intraoral approach to the mental nerve block.

Advance the needle one-third the depth of the mandibular body and contact the mandible. Inject 1 to 2 mL of local anesthetic solution.

US-guided block: The nerve can also be located exiting the foramen with US. Find the foramen where the nerve exits with US. Inject 1.5 mL of the local anesthetic just outside the foramen. **Do not inject into the foramen as this can put pressure on the nerve and result in necrosis.**

Remarks: This is the preferred approach to block the mental nerve. The intraoral route results in the patient experiencing less pain than the extraoral route.

GREATER OCCIPITAL NERVE BLOCK

Anatomy: The greater occipital nerve is a branch of the dorsal ramus of the second cervical nerve. It provides sensory innervation to the posterior neck, extending superiorly to the vertex of the scalp (**Figure 156-9**). It emerges on the posterosuperior neck just below the line connecting the external occipital protuberance and the mastoid process (**Figure 156-10**). The posterior occipital artery accompanies the greater occipital nerve.

Patient positioning: Place the patient prone.

Landmarks: Identify the external occipital protuberance and mastoid process by palpation (**Figure 156-10A**). Connect these landmarks with a line. Identify the occipital artery by its palpable pulse approximately one-third the distance from the external occipital protuberance.

Needle insertion and direction: Place a skin wheal of local anesthetic solution over the pulse of the occipital artery. Insert a 25 gauge needle 1 to 2 mm to the left of the occipital artery pulse. Inject 1 mL of local anesthetic solution. Redirect the needle 1 to 2 mm to the right of the pulse and inject 1 mL of local anesthetic solution.

US-guided block: Several small studies have shown that these injections can be performed safely.^{22,23} Place the patient prone. Place the linear transducer below the external occipital protuberance in a transverse orientation (**Figure 156-10C**). Turn on the color Doppler box. Slide the transducer laterally until the occipital artery is seen. The greater occipital nerve is medial to the occipital artery (**Figure 156-10D**). Insert a 25 gauge needle under the lateral border of the transducer. Advance the needle to the nerve and inject 1 to 2 mL of local anesthetic solution.

FIGURE 156-9. The cutaneous nerve supply to the face, scalp, and upper neck.

FIGURE 156-10. Regional anesthesia of the posterolateral scalp. **A.** The greater occipital nerve block. **B.** The lesser occipital and great auricular nerve blocks. **C.** Transducer placement for blocking the greater occipital nerve. **D.** US image of the greater occipital nerve.

Remarks: This block is useful for laceration repair as well as relief of occipital muscular or tension headaches.²⁴ If the pulse of the posterior occipital artery is not palpable, divide the line between the external occipital protuberance and the mastoid process into thirds. Infiltrate the middle third subcutaneously with 5 to 8 mL of local anesthetic solution (**Figure 156-10A**). This technique will also anesthetize the lesser occipital nerve.

LESSER OCCIPITAL NERVE BLOCK

Anatomy: The lesser occipital nerve is a branch of the cervical plexus. It provides sensory innervation to the skin and scalp between the ear and the mastoid process (**Figure 156-9**). It emerges at the middle third of the posterior border of the sternocleidomastoid muscle and travels superiorly toward the mastoid process (**Figure 156-10**).

Patient positioning: Place the patient supine or sitting with their head turned toward the side opposite that being anesthetized.

Landmarks: Identify the mastoid process by palpation.

Needle insertion and direction: Place a skin wheal of local anesthetic solution just posterior to the mastoid process. Insert a 25 gauge needle directed anteriorly through the skin wheal. Advance the needle while infiltrating local anesthetic solution subcutaneously until the posterior ear is contacted (**Figure 156-10B**). This requires 3 to 7 mL of local anesthetic solution.

Remarks: The lesser occipital nerve can be blocked at the level of the cervical plexus. Refer to the section on cervical plexus blockade below.

GREAT AURICULAR NERVE BLOCK

Anatomy: The great auricular nerve is a branch of the cervical plexus. It emerges at the middle third of the posterior border of the sternocleidomastoid muscle and travels superiorly with the external jugular vein (**Figure 156-10B**). This nerve provides sensory innervation to the skin and scalp behind the ear, the posterior ear, and the lobule (**Figure 156-9**).

Patient positioning: Place the patient supine with their head turned toward the side opposite that being anesthetized.

Landmarks: Identify the lobule of the ear, the mastoid process, and the sulcus behind the ear.

Needle insertion and direction: Place a skin wheal of local anesthetic solution just posterior to the mastoid process. Insert a 25 gauge needle directed anteriorly through the skin wheal. Advance the needle while infiltrating local anesthetic solution subcutaneously until the posterior ear is contacted (**Figure 156-10B**). This requires 3 to 7 mL of local anesthetic solution. Complete and successful anesthesia occurs within 10 minutes.

US-guided block: The nerve can also be blocked with US.²⁵ Find the nerve with US. Aim and advance the needle toward the nerve. Inject the 1.5 mL of the local anesthetic. The anesthetic spreads around the nerve to obtain the “donut sign.”

Remarks: The great auricular nerve block is indicated for lacerations of the auricle, debridement, and hematoma evacuations.²⁵ It is rarely performed without simultaneous blockade of the auriculotemporal nerve. The great auricular nerve can be blocked at the

FIGURE 156-11. The scalp block. **A.** The sensory innervation of the scalp. **B.** Local anesthetic solution is injected subcutaneously along the base of the scalp.

level of the cervical plexus. Refer to the section on cervical plexus blockade below.

SCALP BLOCK

Anatomy: The scalp receives its sensory innervation from branches of the trigeminal nerve anteriorly and the cervical plexus posteriorly (Figure 156-11). The scalp may be anesthetized anywhere along the anterior midline to the posterior midline. This involves blocking the supratrochlear, supraorbital, auriculotemporal, lesser occipital, great auricular, and greater occipital nerves.

Patient positioning: Place the patient supine with their head turned toward the side opposite that being anesthetized.

Landmarks: Identify the glabella and the external occipital protuberance by palpation.

Needle insertion and direction: Place a skin wheal of local anesthetic solution over the glabella. Insert a 25 gauge needle through the skin wheal. Infiltrate a continuous line of local anesthetic solution subcutaneously between the glabella and the external occipital protuberance (Figure 156-11B). This requires 15 to 20 mL of local anesthetic solution.

Remarks: Infiltrate the local anesthetic solution subcutaneously along the scalp base inferior to the area in which the procedures will be performed to block only a portion of the scalp. It is useful to add epinephrine (1:200,000) to the local anesthetic solution to cause vasoconstriction and prevent excessive blood loss. Significant systemic absorption of the local anesthetic agent does not occur despite the extensive vascularity of the scalp. Scalp blocks provide anesthesia for laceration repair, drainage of superficial abscesses, and the exploration of scalp wounds. Complications are fairly rare.²⁶ There is a case report of a temporary facial nerve palsy after a scalp block.²⁷

EXTERNAL EAR BLOCK

Anatomy: The ear is a difficult structure to anesthetize. It is innervated by a large number of sensory fibers that originate from the cervical plexus, the trigeminal nerve, and the vagus nerve. The

external ear, or pinna, is innervated by the cervical plexus and the auriculotemporal branch of the trigeminal nerve (Figures 156-9 and 156-11).

Patient positioning: Place the patient supine or sitting upright with their head turned toward the side opposite that being anesthetized.

Landmarks: Identify the angle of the mandible by palpation.

Needle insertion and direction: Place a skin wheal of local anesthetic solution over the angle of the mandible. Insert a 25 gauge needle through the skin wheal. Infiltrate local anesthetic solution subcutaneously in an anterior and superior direction, from the angle of the mandible to the superior surface of the ear, to block the auriculotemporal nerve (Figure 156-12A). Infiltrate local anesthetic solution subcutaneously in a posterior and superior direction, from the angle of the mandible to the superior surface of the ear, to block the great auricular and lesser occipital nerves (Figure 156-12A). This requires a total of 8 to 10 mL of local anesthetic solution.

Remarks: Some may prefer to anesthetize the auriculotemporal nerve trunk by injecting local anesthetic solution just above the posterior aspect of the zygomatic arch (Figure 156-12B). It requires less local anesthetic solution and hurts less than subcutaneous infiltration. An alternative technique is to circumferentially infiltrate local anesthetic solution subcutaneously around the ear (Figure 156-12C).²⁸

EXTERNAL AUDITORY CANAL BLOCK

Anatomy: The external auditory canal (and the tympanic membrane) receives its innervation from the auriculotemporal nerve and the vagus nerve.

Patient positioning: Place the patient sitting upright or supine with their head turned toward the side opposite that being anesthetized.

Landmarks: Identify the helix, the tragus, and the lobule of the ear to be anesthetized (Figure 156-13).

Needle insertion and direction: Anesthetize the external auditory canal using a four-quadrant block (Figure 156-13). Insert a 25 gauge needle, advance it 0.5 to 0.75 cm, and inject 1 mL of local anesthetic solution at each of the four landmarks identified in Figure 156-13.

FIGURE 156-12. The external ear block. **A.** Infiltration of local anesthetic solution from the angle of the mandible to the anterior (1) and posterior (2) superior surfaces of the ear. **B.** The site for anesthetizing the trunk of the auriculotemporal nerve. **C.** An alternative method.

Remarks: This block can be quite painful for the patient. The authors recommend to first anesthetize the external ear before anesthetizing the external auditory canal. This block also anesthetizes the tympanic membrane.

CERVICAL PLEXUS BLOCK

Anatomy: The cervical plexus originates from the anterior rami of cervical nerves two through four. These rami form numerous loops that anastomose to form nerves that provide sensory innervation to the anterolateral neck, the scalp, the ear, and the infraclavicular area. The four nerves of the cervical plexus become superficial at the mid-portion of the posterior border of the sternocleidomastoid muscle and then distribute to their respective sensory areas (**Figure 156-14A**). The cervical plexus provides motor innervation to the strap muscles of the neck.

The four superficial nerves of the cervical plexus are the lesser occipital nerve, the great auricular nerve, the anterior (or transverse) cervical nerve, and the supraclavicular nerve (**Figure 156-14A**). The lesser occipital nerve travels superiorly and posteriorly to provide sensory innervation to part of the posterior surface of the upper ear and the postauricular skin. The great auricular nerve travels

superiorly and anteriorly to provide sensory innervation to the skin over the posterior surface of the ear, the anterior lower half of the ear, and over the angle of the mandible. The anterior, or transverse, cervical nerve of the neck travels anteriorly to provide sensory innervation to the skin of the neck from the inferior border of the mandible to the sternum. The supraclavicular nerves travel and innervate the skin of the clavicle down to the second rib.

Patient positioning: Place the patient supine with their head turned toward the side opposite of that being anesthetized.

Landmarks: Identify the posterior border of the sternocleidomastoid muscle by palpation. Divide this border into thirds.

Needle insertion and direction: Place a skin wheal of local anesthetic solution over the middle third of the posterior border of the sternocleidomastoid muscle. Insert a needle through the skin wheal. Infiltrate 5 to 10 mL of local anesthetic solution subcutaneously over the middle third of the posterior border of the sternocleidomastoid muscle (**Figure 156-14B**).

Remarks: This block is useful when managing burns or suturing lacerations on the anterolateral neck. The complications of this block include a resultant Horner's syndrome.²⁹ There is no advantage to using US with this block since the landmark is easy to find and the cervical plexus is consistent in its location.³⁰

REGIONAL ANESTHESIA TECHNIQUES FOR THE UPPER EXTREMITY

BRACHIAL PLEXUS BLOCK

The brachial plexus innervates the entire upper extremity. Blockade of the brachial plexus can be performed to repair tendons or extensive lacerations, to reduce fractures and dislocations, or to provide anesthesia for burn care to name a few uses. Protect the arm from injury if this procedure is to be performed by properly supporting the arm, padding the ulnar nerve and pressure points, and not extending or displacing the arm posteriorly.

The brachial plexus arises from the C5 to T1 nerve roots (**Figure 156-15**). The nerve roots fuse to form three trunks. Each trunk divides into an anterior and posterior division that then redistributes to form the lateral, medial, and posterior cords. These cords divide in the region of the axilla to form the musculocutaneous nerve, the median nerve, the ulnar nerve, the axillary nerve,

FIGURE 156-13. External auditory canal block. Inject local anesthetic solution at each of the four landmarks. This block also anesthetizes the tympanic membrane.

FIGURE 156-14. The cervical plexus block. **A.** The cutaneous nerves of the cervical plexus. **B.** Injection of local anesthetic solution posterior to the middle third of the sternocleidomastoid muscle.

the radial nerve, and several cutaneous nerves. The brachial plexus crosses the midclavicle to enter the axilla (**Figure 156-16A**).

The brachial plexus may be blocked from the supraclavicular, interscalene, infraclavicular, or axillary approach. The preferred non-US method for the Emergency Physician is the axillary block which will be described in detail. The other blocks will also be discussed. The lack of US use with these other nerve block techniques requires the use of a nerve stimulator and they have a high risk of associated complications. Blockade of the brachial plexus can result in hemidiaphragm paresis, even if using US for guidance.^{31,32}

BRACHIAL PLEXUS BLOCK, SUPRACLAVICULAR APPROACH

Anatomy: The anatomy of the brachial plexus is described above. This approach blocks the brachial plexus at the level of the trunks where it is most compactly arranged.

Patient positioning: Place the patient supine with their head turned 45° from the midline and toward the side opposite that being anesthetized (**Figure 156-16A**). Place the ipsilateral arm in any position of comfort for the patient.

Landmarks: The subclavian artery is the main landmark. Palpate the subclavian artery immediately lateral to the clavicular head of the sternocleidomastoid muscle in the interscalene groove. Identify the midpoint of the clavicle.

Needle insertion and direction: Place a skin wheal of local anesthetic solution 2 cm above the midclavicle. Insert a 25 gauge needle directed caudally through the skin wheal (**Figures 156-16B and 156-16C**). Advance the needle until the patient experiences paresthesias. Withdraw the needle 1 mm and allow the paresthesias to resolve. Aspirate to ensure that the tip of the needle is not within a blood vessel. Inject 40 mL of local anesthetic solution. Reduce the volume based on the patient's body size and the maximal allowable dose to prevent toxicity.

FIGURE 156-15. The brachial plexus. **A.** The anatomy of the brachial plexus. **B.** The brachial plexus is contained within a sheath. The subclavian artery and vein enter the sheath at the level of the clavicle.

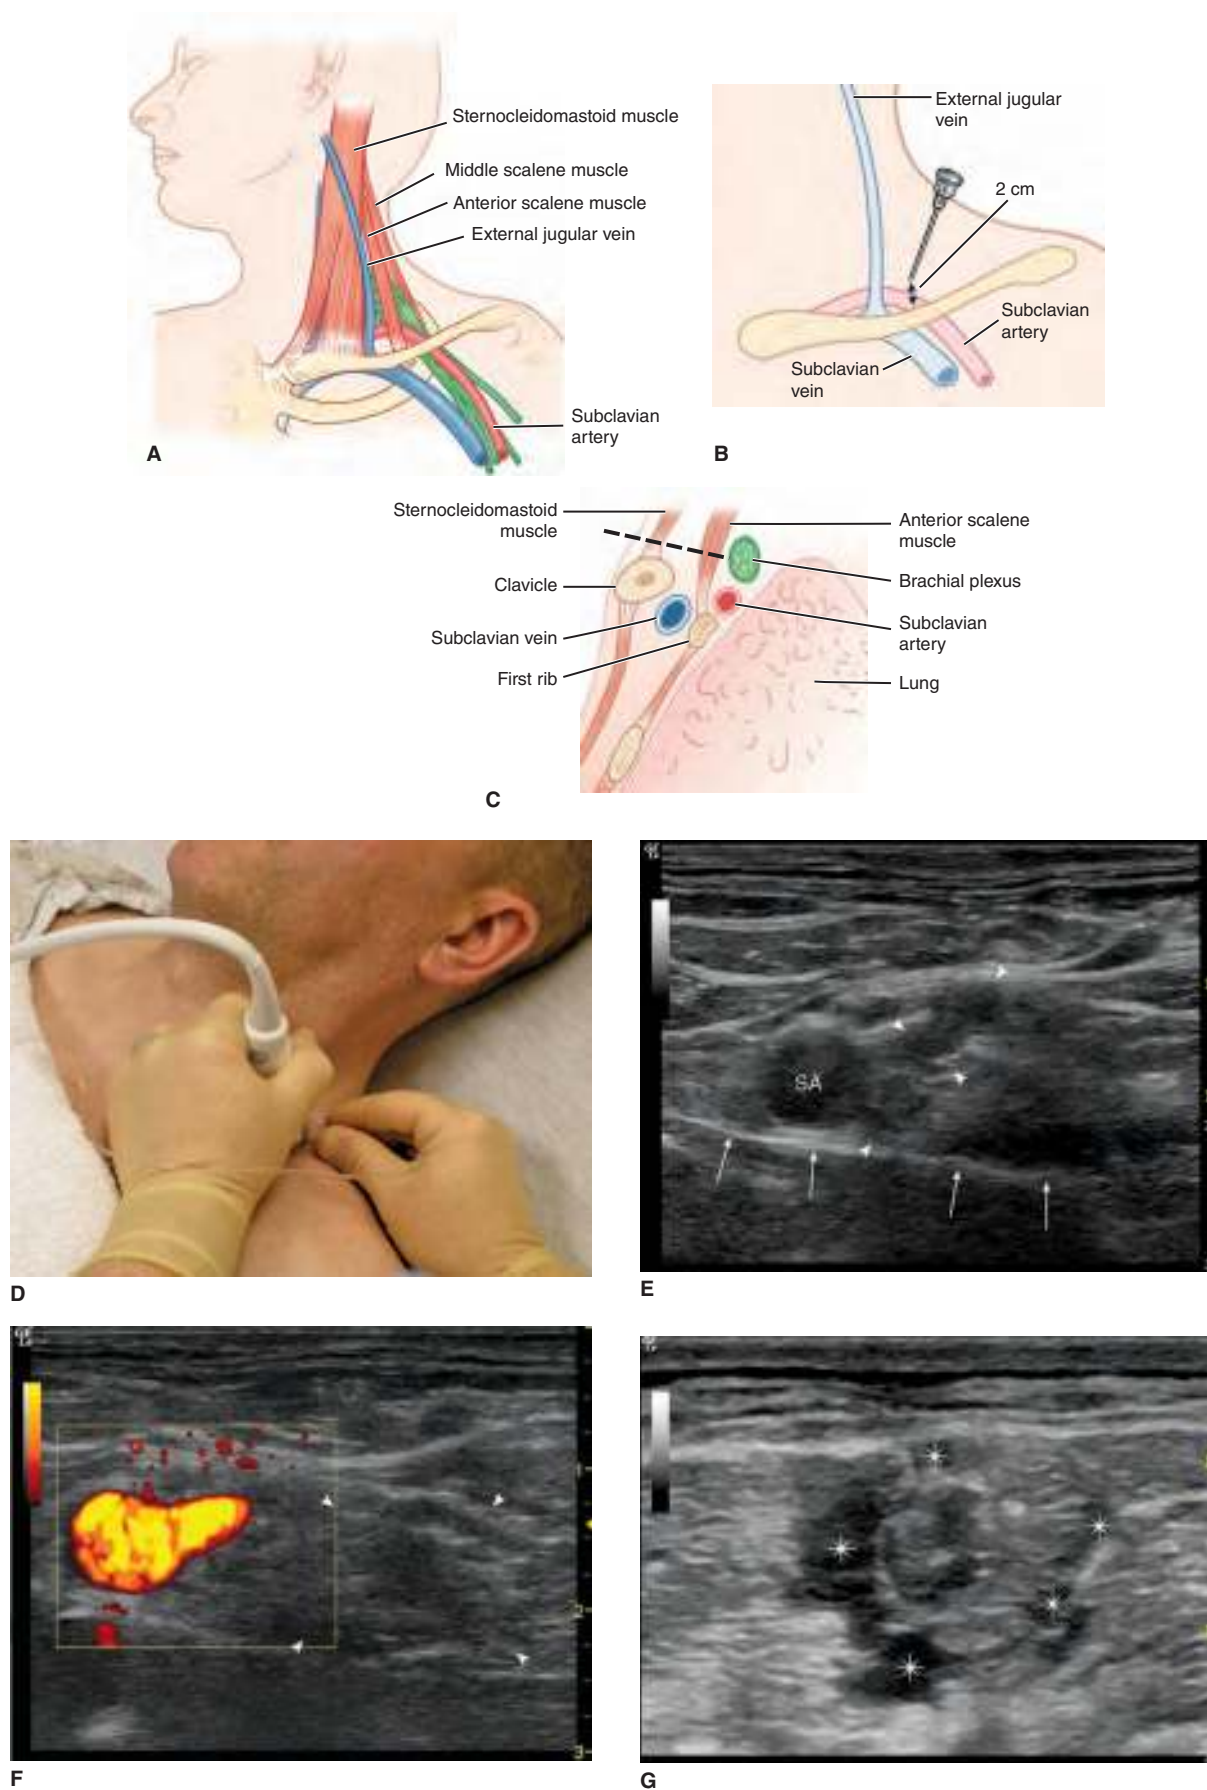

FIGURE 156-16. The supraclavicular approach to the brachial plexus block. **A.** The course of the brachial plexus. **B.** The needle is inserted perpendicular to the skin and 2 cm superior to the middle of the clavicle. **C.** Sagittal section demonstrating the trajectory of the needle (*dotted line*). **D.** US transducer and needle placement. **E.** The supraclavicular brachial plexus (*arrowheads*) is adjacent to the subclavian artery (SA). The first rib is denoted by the *arrows*. **F.** Color Doppler of the supraclavicular brachial plexus (*arrowheads*). The subclavian artery and a branch are visible in color. **G.** The “donut sign.” Local anesthetic solution (*) surrounds the nerve bundles.

US-guided block: This nerve can be blocked with the aid of US.³³ Place the US transducer in an oblique coronal plane above the clavicle and lateral to the sternocleidomastoid muscle (**Figure 156-16D**). Locate the subclavian artery. It is a pulsatile, round, and hypoechoic structure in cross-section. The trunks of the brachial plexus are located adjacent to the subclavian artery (**Figure 156-16E**). Posterior to the subclavian artery lies the first rib and the pleural line can be seen sliding in real time. **Use color/power Doppler to confirm the location of the subclavian artery and any branches or take-offs, all of which must be avoided (Figure 156-16F).** Anesthetize the skin. Position the spinal needle lateral to the US transducer and parallel to its long axis. Slowly insert and advance the needle. Visualize the entire length of the needle as it is introduced through the subcutaneous tissue toward the brachial plexus. Advance the needle through the nerve sheath. Aspirate to ensure the needle tip is not in a blood vessel. Inject a test dose of 1 to 2 mL of local anesthetic solution. Watch the spread of anesthetic around the nerves. If it is satisfactory, inject the remainder of the local anesthetic solution to achieve the “donut sign” (**Figure 156-16G**). If the test dose is not satisfactory, reposition the needle and inject another test dose.

Remarks: This block is characterized by a quick onset of anesthesia and a complete block. A high volume of anesthetic is required with a quick onset of anesthesia. There is no chance of missing peripheral or proximal nerve branches because of failure of the local anesthetic solution to spread along the sheath of the brachial plexus. Unfortunately, this technique is difficult to teach and to master without considerable experience. This technique has a high incidence of an iatrogenic pneumothorax, reportedly up to 6%. Other complications include blockade of the phrenic nerve, subclavian artery puncture, and Horner’s syndrome. Unintentional intravascular injection can result in high blood levels of the local anesthetic agent.

BRACHIAL PLEXUS BLOCK, INTERSCALENE APPROACH

Anatomy: The anatomy of the brachial plexus is described above. This approach blocks the brachial plexus at the level of the trunks (**Figure 156-17A**).

Patient positioning: Place the patient supine with their head turned 45° from midline and toward the side opposite that being anesthetized (**Figure 156-17A**). Place the ipsilateral arm in any position of comfort for the patient.

Landmarks: Identify the posterior border of the clavicular head of the sternocleidomastoid muscle by palpation. Move the palpating finger laterally until it rolls into the interscalene groove between the anterior and middle scalene muscles at the level of the cricoid cartilage (**Figure 156-17B**).

Needle insertion and direction: Place a skin wheal of local anesthetic solution in the interscalene groove at the level of the cricoid cartilage. Slowly insert a 25 gauge needle through the skin wheal in a dorsal, medial, and caudal direction (**Figure 156-17B**). Advance the needle until the patient experiences paresthesias. Withdraw the needle 1 mm and allow the paresthesias to resolve. Aspirate to ensure that the tip of the needle is not within a blood vessel. Inject 30 to 40 mL of local anesthetic solution. Reduce the volume based on the patient’s body size and the maximal allowable dose to prevent toxicity.

US-guided block: The brachial plexus can be blocked by performing the interscalene block with the aid of US.^{34,35} This block is performed at the level of the internal jugular vein and carotid artery in the neck. Place the US transducer on the neck less than a third of the way up from the clavicle (**Figure 156-17C**). Identify the carotid artery and internal jugular vein. Move the US transducer laterally to find the muscle bellies of the anterior and middle scalene muscles

(**Figure 156-17D**). Between the muscles lie the nerve roots of the brachial plexus in cross-section. It is represented by hypoechoic circles within the hyperechoic rings of the nerve sheaths (**Figure 156-17D**). **Use color Doppler to identify any blood vessels in the field and note their location so as to avoid them.** Anesthetize the skin. Using a posterior approach, insert the spinal needle connected by extension tubing to a 20 mL syringe filled with local anesthetic solution. Advance the needle and visualize it approaching the brachial plexus. The needle path will usually go through the middle scalene muscle. Once the brachial plexus is close to the needle tip, use a short and controlled jab to penetrate through the nerve sheath. Aspirate to verify that the needle tip is not in a blood vessel. Instruct an assistant to deliver a test dose of 1 to 2 mL of local anesthetic solution. If the anesthetic spreads around the nerves, slowly deliver the remainder of the local anesthetic solution to obtain the “donut sign.” If the test dose is not satisfactory, reposition the needle and inject another test dose.

Remarks: The advantages and disadvantages are similar to those of the supraclavicular approach with the exception of possibly not achieving anesthesia of the lower trunk. This may require supplementary blockade of the median and ulnar nerves. The interscalene brachial plexus block, although ideal for regional anesthesia of the shoulder, has been associated with recurrent laryngeal nerve paralysis and an almost 100% incidence of phrenic nerve paralysis.³⁶ This can be significant in patients with respiratory comorbidities (e.g., chronic obstructive pulmonary disease, obesity).³⁷ The supraclavicular brachial plexus block is associated with lower rates of these complications.³

BRACHIAL PLEXUS BLOCK, AXILLARY APPROACH

Anatomy: The anatomy of the axillary brachial plexus nerve block is rather simple. The neurovascular bundle is easily found at the anterior axillary fold by palpating for the pulsations of the axillary artery. The neurovascular bundle is surrounded by the fibrous axillary sheath (**Figure 156-18A**). The axillary sheath is bound medially by skin and connective tissue, anteriorly by the biceps and coracobrachialis muscles, inferiorly by the triceps muscle, and laterally by the neck of the humerus. The axillary artery is the central reference structure within the neurovascular bundle. Within the axillary sheath the median nerve is anterior, the radial nerve is posterolateral, and the ulnar nerve is posterior to the axillary artery (**Figure 156-18A**). The axillary vein is medial to the artery. The medial antebrachial cutaneous nerve and the medial brachial cutaneous nerve are medial to the artery (**Figure 156-18A**). The only sensory nerve outside the neurovascular bundle is the musculocutaneous nerve. This nerve exits the axillary sheath as it crosses the clavicle.

Patient positioning: Place the patient supine with their head turned toward the side opposite that being anesthetized (**Figure 156-18B**). Abduct the arm 90°. Flex the elbow 90° so that the forearm is parallel to the long axis of the body and the palm is facing upward.

Landmarks: Identify the brachial artery by its palpable pulse. Trace it proximally to the anterior axillary fold formed by the pectoralis major muscle. Use the index and middle fingers of the non-dominant hand to secure the neurovascular bundle (identified by the pulse) against the humerus (**Figure 156-18B**).

Needle insertion and direction: Place the skin wheal of local anesthetic solution overlying the axillary artery pulse just posterior to the anterior axillary fold. Insert a 22 gauge spinal needle just above the fingertip on the axillary pulse, directed toward the apex of the axilla, and in the direction of the neurovascular bundle (**Figure 156-18B**). Advance the needle. A “pop” will be felt as the axillary sheath is penetrated. The correct needle position is

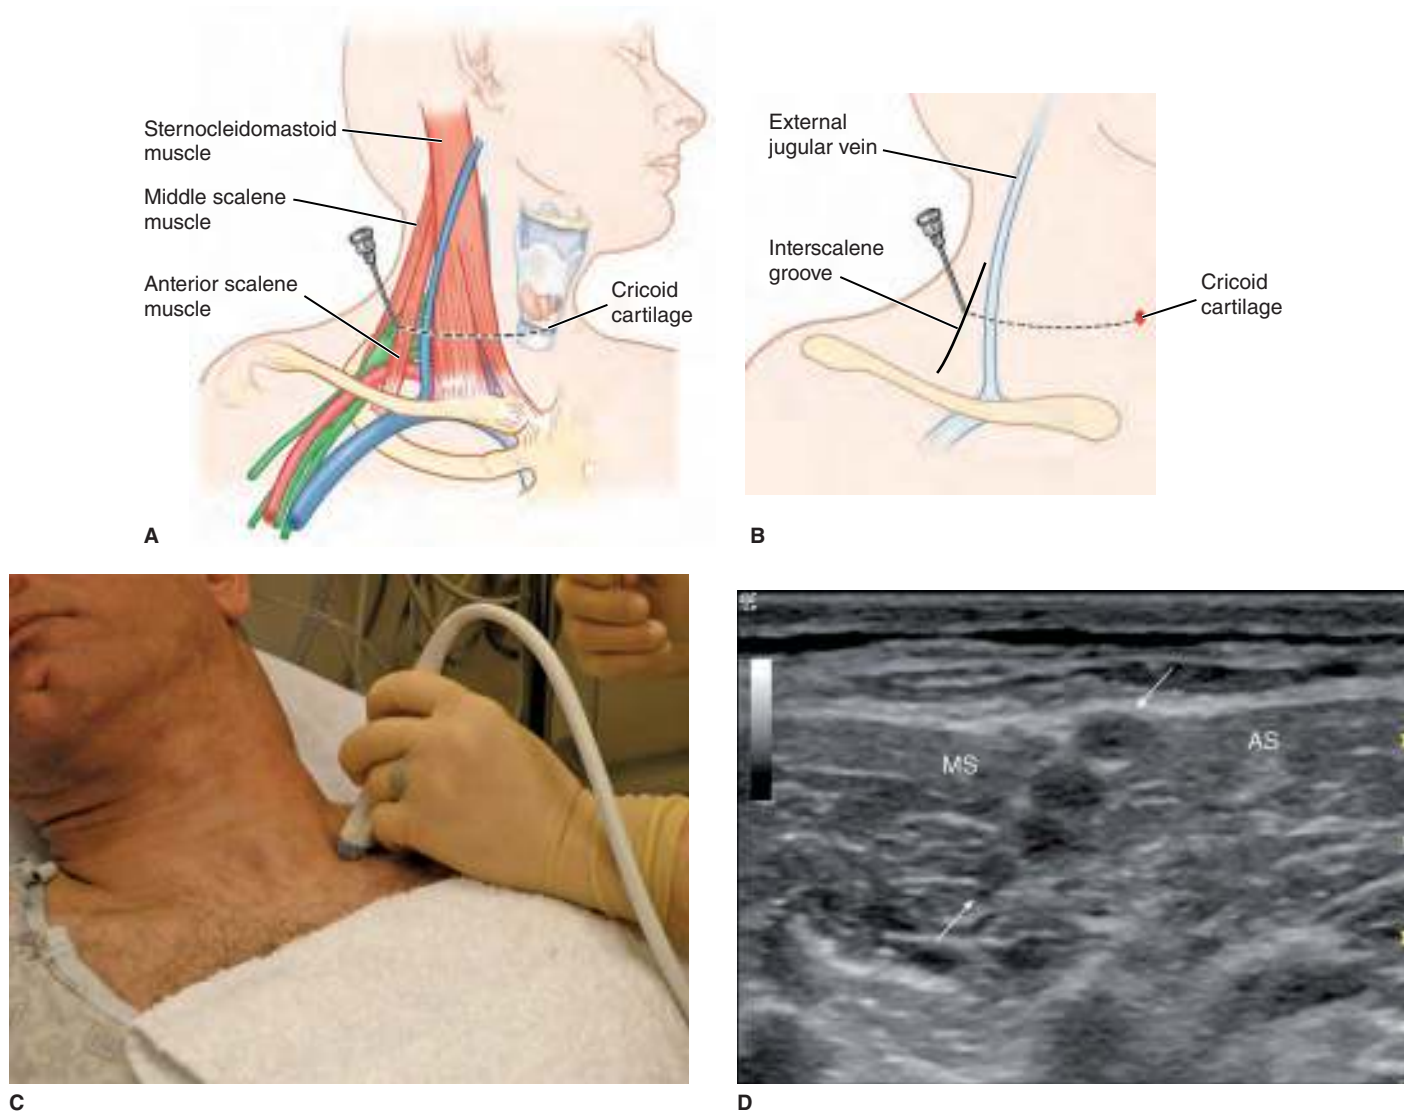

FIGURE 156-17. The interscalene approach to the brachial plexus block. **A.** The anatomy of the region. **B.** The needle is inserted into the interscalene groove at the level of the cricoid cartilage. **C.** US transducer placement. **D.** The brachial plexus (between the arrows) is located between the anterior scalene (AS) and the middle scalene (MS) muscles.

confirmed by eliciting paresthesias, observing blood flow in the needle, or observing pulsations of the needle that match the pulse. Instruct an assistant to attach the distal end of intravenous extension tubing to the hub of the needle and the proximal end to a 60 mL syringe containing local anesthetic solution. The Emergency Physician must always maintain pressure against the neurovascular bundle with the nondominant hand while stabilizing the needle with the dominant hand. Instruct the assistant to aspirate to ensure that the tip of the needle is not within a blood vessel. Withdraw the needle 2 mm if blood flow or paresthesias are elicited.

Apply digital pressure to the neurovascular bundle just distal to the tip of the needle with the nondominant fingers. This prevents the local anesthetic solution from flowing distally. Inject the local anesthetic solution into the axillary sheath after the paresthesias have resolved and a negative aspiration has been achieved. Instruct the assistant to inject a volume of approximately 40 mL in the adult patient. This volume has been shown to consistently block the entire brachial plexus. Reduce the volume based on the patient's body size and the maximal allowable dose to prevent toxicity. **Continue to apply digital pressure to the neurovascular bundle just distal to the needle during and after injection of the local anesthetic solution.**

Withdraw the needle while the assistant simultaneously injects 3 to 5 mL of local anesthetic solution into the subcutaneous tissue. This blocks the medial brachial cutaneous nerve and the intercosto-brachial nerve. Abduct the patient's arm 30° to 45° after the needle is withdrawn. Maintain this position while continuing to apply digital pressure to the neurovascular bundle just distal to the needle insertion site, for 2 to 3 minutes.

US-guided block: The brachial plexus can be blocked by performing the axillary block with the aid of US. This block is performed at the level of the terminal branches of the brachial plexus within the axillary sheath. These branches are visualized as hyperechoic nodules around the pulsatile and hypoechoic axillary artery (Figures 156-18D and 156-18E). Place the US transducer with the marker pointing cephalad at the superior axillary crease (Figure 156-18F). Locate the axillary artery and vein in cross-section (Figure 156-18G). The musculocutaneous nerve can be seen between the biceps muscle and the coracobrachialis muscle. Use color Doppler to confirm the location of the axillary artery, vein, and any branches or take-offs (Figure 156-18G). Anesthetize the skin. Position the spinal needle inferior or superior to the long axis of the US transducer (Figure 156-18F). Slowly insert and advance the needle. Visualize the entire length of the needle as it is advanced. Aim the needle between the axillary artery and vein.

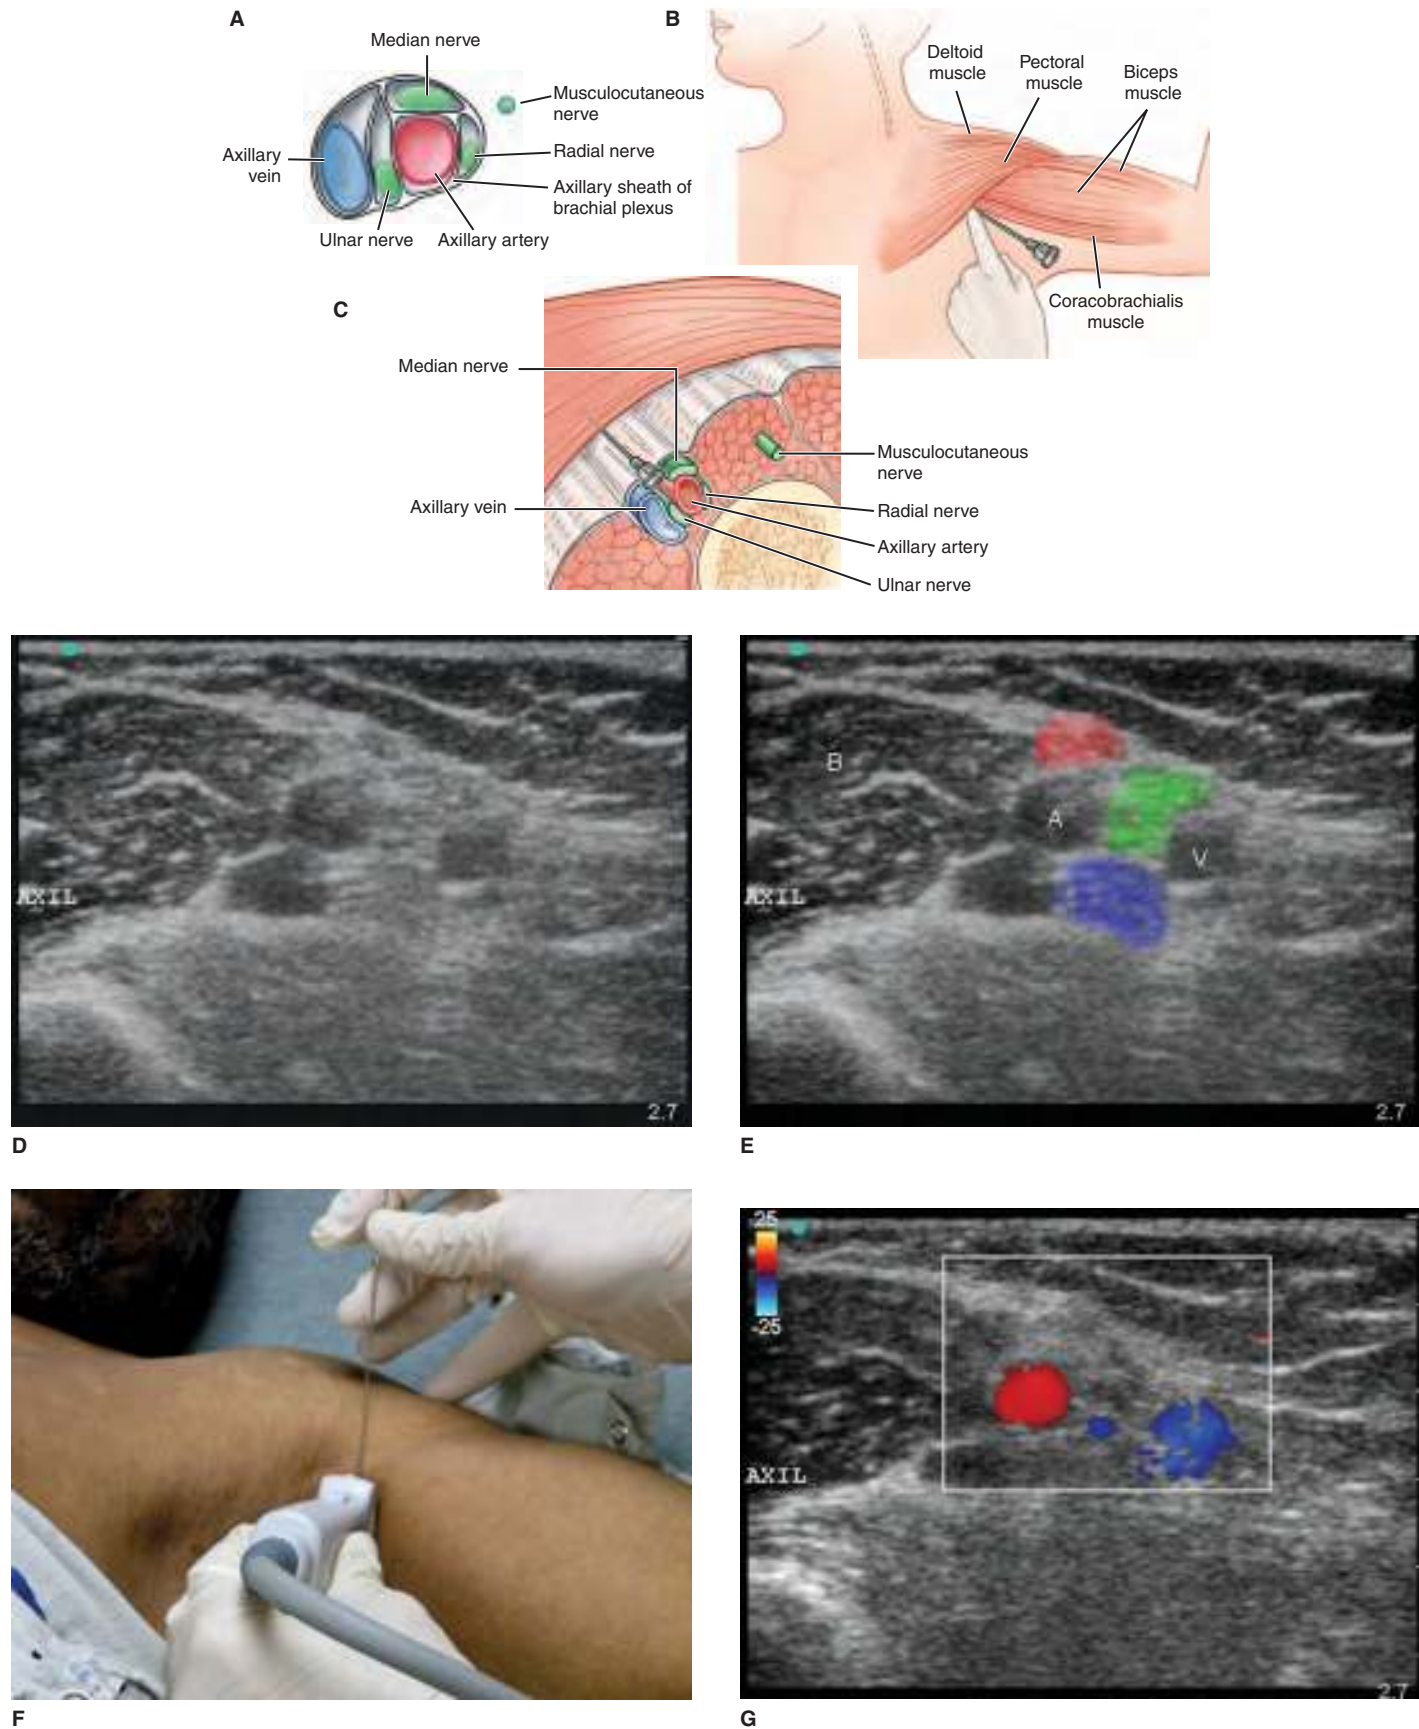

FIGURE 156-18. The axillary approach to the brachial plexus block. **A.** The topographical arrangement of the contents of the axillary sheath at the level of the blockade. **B.** The patient is positioned and the axillary artery pulse is palpated with one finger. The needle is inserted above the pulse and along the course of the axillary sheath. **C.** The needle may travel above the sheath and enter it at a higher level. **D.** US image of the axillary brachial plexus. **E.** Same image as in part **D** with labels (A, axillary artery; B, biceps muscle; V, axillary vein; red oval, median nerve; green oval, ulnar nerve; blue oval, radial nerve). **F.** US transducer and needle placement. **G.** Color Doppler of the axillary artery (red) and vein (blue).

Advance through the nerve sheath. Aspirate to ensure the needle tip is not in a blood vessel. Inject a test dose of 1 to 2 mL of local anesthetic solution. Watch the spread of local anesthetic solution around the subclavian artery. If it is satisfactory, inject the remainder of the local anesthetic solution to produce the “donut sign.” If the test dose is not satisfactory, reposition the needle and inject another test dose.

Remarks: The axillary approach to the brachial plexus is the most commonly used and preferred technique. The procedure is easily mastered, has no major complications, and is easily performed in the obese patient. The disadvantages of this technique include insufficient anesthesia of the shoulder and upper arm. The musculocutaneous nerve provides sensory innervation to the radial aspect of the forearm and may be missed by the local anesthetic agent. The subcutaneous infiltration of local anesthetic solution usually blocks the musculocutaneous nerve. **Proximal flow of the local anesthetic solution is required to ensure adequate anesthesia.** Abduction of the arm while maintaining pressure on the neurovascular bundle allows proximal flow of the local anesthetic solution. It also prevents the humeral head from limiting proximal spread due to compression of the brachial plexus.

BRACHIAL PLEXUS BLOCK, INFRACLAVICULAR APPROACH

This approach to the brachial plexus has many advantages and few serious complications. Unfortunately, this technique requires considerable experience on the part of the Emergency Physician and a nerve stimulator to locate the brachial plexus (Figures 156-19A and 156-19B). For these reasons, the anatomic landmark approach will not be described. The US-guided technique is described below.

Anatomy: The anatomy of the brachial plexus is described above. This approach blocks the brachial plexus at the level of the cords (Figure 156-17A).

Patient positioning: Place the patient supine with their head turned 45° from midline and toward the side opposite that being anesthetized (Figure 156-19A). Place the ipsilateral arm extended 90°.

Landmarks: Identify the middle third of the clavicle.

Infracavicular Block. The brachial plexus can be blocked by performing the infracavicular block with the aid of US.³⁶ This block is performed below the clavicle. The cords of the brachial plexus lie below the pectoralis major and minor muscles. They appear as distinct hyperechoic nodules positioned laterally, medially, and

posteriorly around the subclavian artery (Figures 156-19C and 156-19D). Prep and drape the infraclavicular region. Place the US transducer with the marker pointing cephalad below the clavicle, medial to the coracoid process (Figure 156-19E). Locate the subclavian artery (which is pulsatile) and vein in cross-section. Use color Doppler to confirm the location of the subclavian artery, vein, and any branches or take-offs (Figure 156-19F). Anesthetize the skin. Position the spinal needle inferior or superior to the long axis of the US transducer (Figure 156-19E). Insert and advance the needle. Visualize the entire length of the needle as it is advanced. Aim the needle between the subclavian artery and vein. Advance the needle. Advance the needle through the nerve sheath. Aspirate to ensure that the needle tip is not in a blood vessel. Inject a test dose of 1 to 2 mL of local anesthetic solution. Watch the spread of local anesthetic solution around the subclavian artery. If satisfactory, inject the remainder of the local anesthetic solution to produce the “donut sign.” If the test dose is not satisfactory, reposition the needle and inject another test dose.

Remarks: This block can result in an iatrogenic pneumothorax due to the proximity of the needle to the lung apex.

MEDIAN NERVE BLOCK, AT THE ELBOW

Anatomy: The median nerve innervates all the muscles of the anterior forearm except the flexor digitorum profundus to the ring and little fingers and the flexor carpi ulnaris.^{13,37,38} It innervates the thenar muscles and the lumbrical muscles to the index and middle fingers in the hand. It provides sensory innervation to the palmar aspect of the thumb, index finger, middle finger, radial portion of the ring finger, and lateral half of the palm (Figure 156-20A). The median nerve provides a variable amount of sensory innervation to the dorsal distal surfaces of the lateral three and one-half fingers.¹³

Patient positioning: Place the patient supine with their arm abducted 45°, the elbow in full extension, and the hand supinated (Figure 156-21A).

Landmarks: Identify the medial and lateral epicondyle of the humerus by palpation. Connect the epicondyles with a straight line (Figure 156-21A). Identify the brachial artery by palpating for its pulse just medial to the biceps tendon and over the line just drawn. Mark the site of the palpable pulse with a marker.

Needle insertion and direction: Place a skin wheal of local anesthetic solution just medial to the pulse at the level of the

FIGURE 156-19. The infraclavicular approach to the brachial plexus block. **A.** Needle insertion and direction. **B.** Sagittal section demonstrating needle insertion into the neurovascular bundle. D

E

F

FIGURE 156-19. (Continued)

FIGURE 156-20. The sensory innervation of the hand. **A.** The median nerve. **B.** The ulnar nerve. **C.** The radial nerve.

intercondylar line. Insert a 25 gauge needle perpendicular to the skin and slowly advance it. If paresthesias are elicited, withdraw the needle 1 to 2 mm and allow the paresthesias to resolve. Inject 3 to 5 mL of local anesthetic solution. If paresthesias are not elicited, slowly move the needle in a fan-like pattern to elicit paresthesias. Withdraw the needle 1 to 2 mm, allow the paresthesias to resolve, and inject 3 to 5 mL of local anesthetic solution.

US-guided block: The nerve can be blocked with the aid of US. Place the US transducer in the crease of the antecubital fossa. Locate the pulsatile brachial artery in the middle of the antecubital fossa (**Figure 156-21B**). Anesthetize the skin medial to the brachial artery. Place the spinal needle inferior to the short axis of the US transducer directly over the median nerve which should be medial to the brachial artery. Only the tip of the needle will be visualized in this view. Insert and advance the needle until its tip is at the median nerve. Aspirate to ensure that the needle tip is not in a blood vessel. Inject a test dose of 1 to 2 mL of local anesthetic solution. Watch the spread of the local anesthetic solution around the median nerve. If satisfactory, inject the remainder of the local anesthetic solution to

produce the “donut sign.” If the test dose is not satisfactory, reposition the needle and inject another test dose.

Remarks: The median nerve has no sensory branches in the forearm. Therefore, there is no advantage to blocking the median nerve at the elbow. Inserting the needle to elicit paresthesias can be quite painful for the patient. Blockade at the wrist is usually easier to perform, especially in obese patients.¹⁰

MEDIAN NERVE BLOCK, AT THE WRIST

Anatomy: The median nerve lies in the carpal tunnel on the volar aspect of the wrist. It is located between the tendons of the flexor carpi radialis and palmaris longus muscles (**Figure 156-21C**). The innervation of the median nerve is described in the previous section.

Patient positioning: Place the patient supine with their arm abducted 45°, the elbow in full extension, and the hand fully supinated (**Figure 156-21A**).

Landmarks: Identify the palmaris longus tendon by flexing the patient’s clenched hand against resistance. Mark the radial border of the palmaris longus tendon. Note the position of the proximal and distal wrist creases.

Needle insertion and direction: Place a skin wheal of local anesthetic solution along the radial border of the palmaris longus tendon between the proximal and distal wrist creases. Insert a 25 gauge needle perpendicular to the skin wheal and advance it slowly (**Figure 156-21C**). If paresthesias are elicited, withdraw the needle 1 to 2 mm and allow them to resolve. Inject 3 to 5 mL of local anesthetic solution. If paresthesias are not elicited, inject 5 to 10 mL of local anesthetic solution. Injection of the local anesthetic solution should not raise a skin wheal and should flow effortlessly if the needle is within the carpal tunnel.¹³

US-guided block: The nerve can be blocked with the aid of US.³⁹ Place the US transducer over the middle of the wrist with the marker pointing laterally (**Figure 156-21D**). The palmaris longus tendon should be visible in the middle of the wrist. The median nerve is hyperechoic and directly lateral to this tendon (**Figure 156-21E**). The radial artery is lateral to the median nerve (**Figure 156-21C**). Anesthetize the skin lateral to the palmaris longus tendon. Place the needle inferior to the short axis of the US transducer and directly over the median nerve (**Figure 156-21D**). Insert and advance the needle until its tip is at the median nerve. Aspirate to ensure that the needle tip is not in a blood vessel. Inject a test dose of 1 to 2 mL of local anesthetic solution. Watch the spread of the local anesthetic solution around the median nerve. If satisfactory, inject the remainder of the local anesthetic solution to produce the “donut sign.” If the test dose is not satisfactory, reposition the needle and inject another test dose.

Remarks: A small percentage of the population (10% to 15%) does not have a palmaris longus tendon.⁴⁰ Identify the flexor carpi radialis tendon by the same method as identifying the palmaris longus tendon. Inject the local anesthetic solution 1 cm medial to the ulnar edge of the flexor carpi radialis tendon between the proximal and distal wrist creases (**Figure 156-21C**). The technique is otherwise as noted above.

ULNAR NERVE BLOCK, AT THE ELBOW

Anatomy: The ulnar nerve lies in the ulnar groove of the humerus at the elbow between the olecranon process and medial condyle of the humerus (**Figure 156-22A**). It provides motor innervation to the flexor carpi ulnaris, the ring and little finger portion of the flexor digitorum profundus, the palmaris brevis, the hypothenar muscles, the third and fourth lumbricals, the interossei, and the adductor pollicis muscles. It provides sensory innervation to the medial one-third to one-half of the palm, the palmar aspect of the ulnar half of the ring finger, and the entire little finger (**Figure 156-20B**). The ulnar nerve

A

B

D

E

C

FIGURE 156-21. The median nerve block. **A.** Blockade at the level of the elbow. **B.** US image of the median nerve at the antecubital fossa. **C.** Blockade at the level of the wrist. **D.** US transducer and needle placement at the wrist. **E.** US image of the volar wrist. The median nerve is the round, hyperechoic structure in the center of the image.

provides sensory innervation to the dorsomedial half of the hand, the little finger, and the ulnar half of the ring finger on the dorsal surface of the hand.⁴¹

Patient positioning: Place the patient supine with their elbow flexed 90° and the shoulder flexed 45° (Figure 156-22A).

Landmarks: Identify the olecranon process and the medial epicondyle of the humerus by palpation. Palpate the groove between the olecranon process and the medial epicondyle. The ulnar nerve is located within this groove.

Needle insertion and direction: Place a skin wheal of local anesthetic solution 1 to 2 cm proximal to the ulnar groove. Insert a 25 gauge needle through the skin wheal and directed toward the ulnar

groove. Aim the needle parallel to the ulnar groove and the course of the nerve (Figure 156-22A). Advance the needle into the ulnar groove and inject 5 to 7 mL of local anesthetic solution. If paresthesias are elicited, withdraw the needle 1 mm and allow them to resolve before injecting the local anesthetic solution.

US-guided block: The nerve can be blocked with the aid of US. Place the US transducer in the crease between the olecranon process and the medial epicondyle with the marker pointing laterally. Two hyperlucent structures should be seen, the medial epicondyle medially and the olecranon process closer to the marker. The ulnar nerve is hyperechoic and courses between these two hyperlucent structures. Anesthetize the skin. Place the needle inferior to the short axis of the

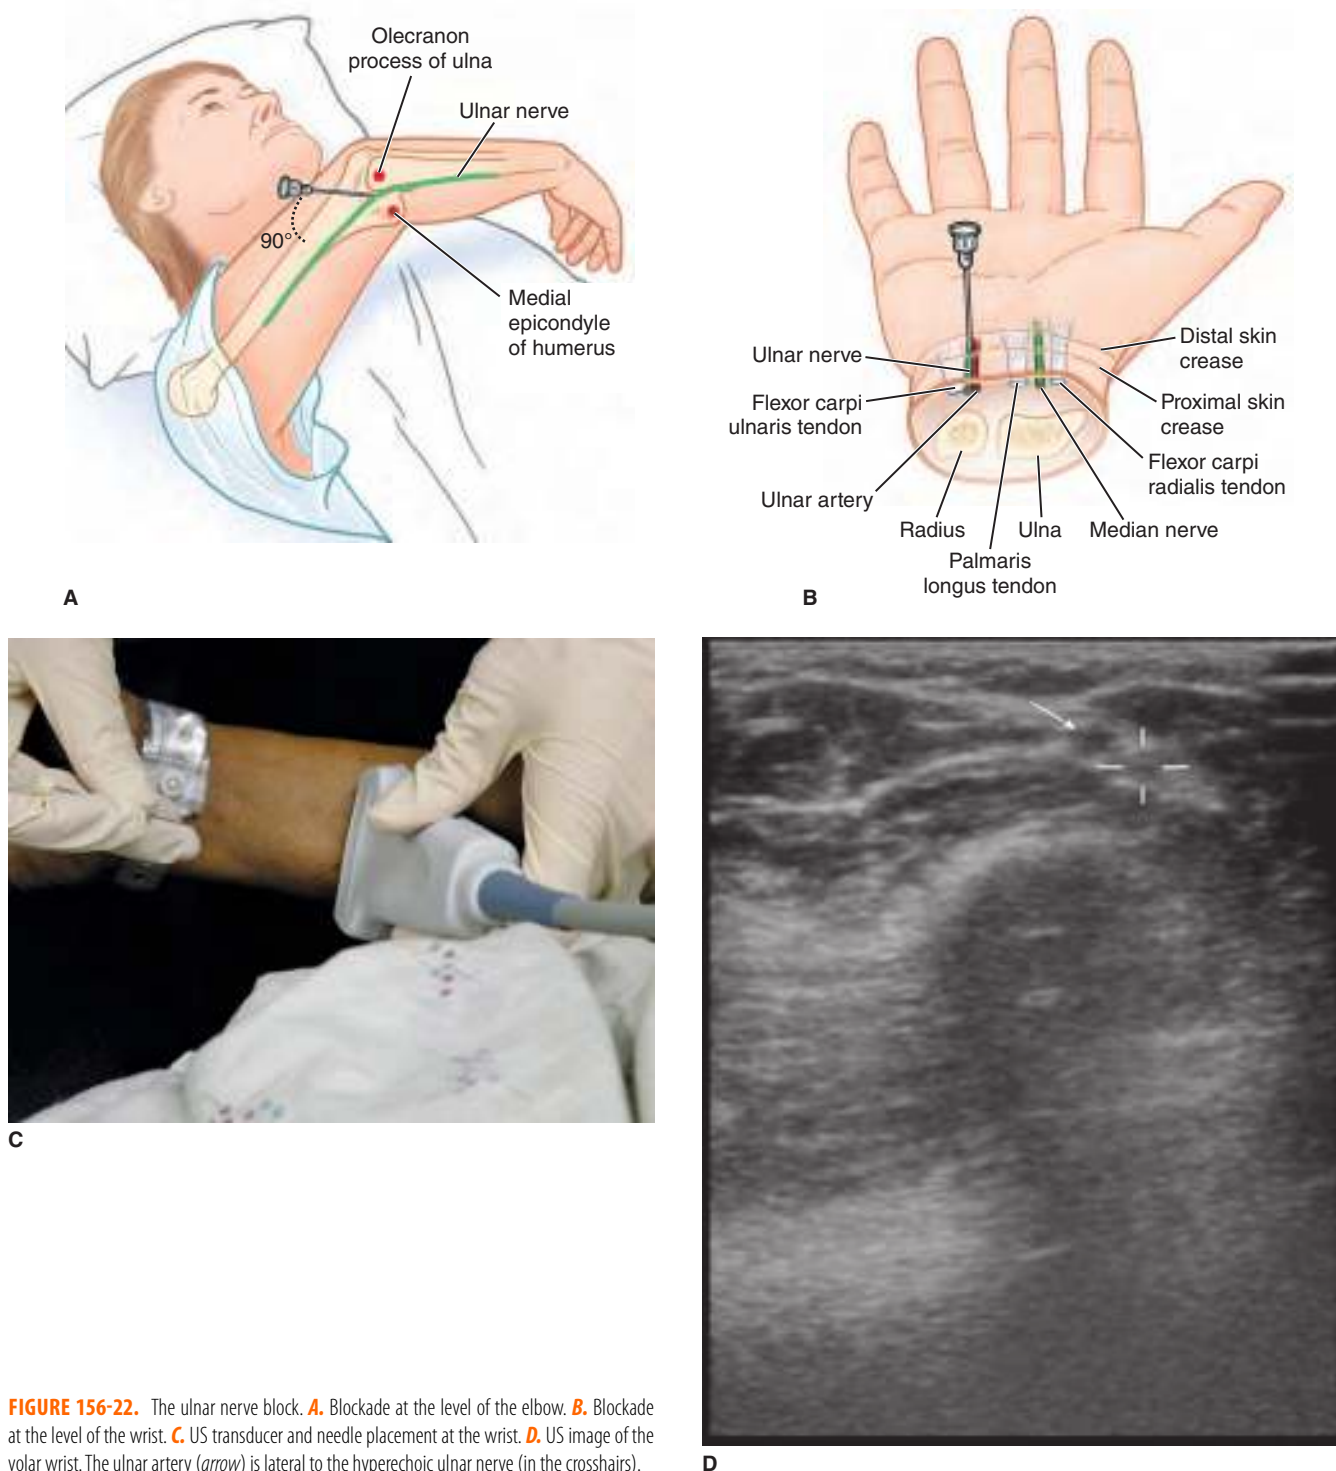

FIGURE 156-22. The ulnar nerve block. **A.** Blockade at the level of the elbow. **B.** Blockade at the level of the wrist. **C.** US transducer and needle placement at the wrist. **D.** US image of the volar wrist. The ulnar artery (arrow) is lateral to the hyperechoic ulnar nerve (in the crosshairs).

US transducer and directly over the ulnar nerve. Only the tip of the needle will be visualized in this view. Insert and advance the needle until its tip is at the ulnar nerve. Aspirate to ensure that the needle tip is not in a blood vessel. Inject a test dose of 1 to 2 mL of local anesthetic solution. Watch the spread of local anesthetic solution around the ulnar nerve. If satisfactory, inject the remainder of the local anesthetic solution to produce the “donut sign.” If the test dose is not satisfactory, reposition the needle and inject another test dose.

Remarks: The ulnar nerve has no sensory branches in the forearm and thus may be blocked at the wrist or at the elbow. Blockade of the ulnar nerve at the elbow is not recommended. A fibrous sheath surrounds the ulnar nerve at the elbow requiring intraneural

injection for a successful blockade. This can lead to residual neuritis and nerve dysfunction. Blocking the ulnar nerve several centimeters above the elbow may prevent these complications. Blockade at the wrist is very reliable and does not have the associated complications as at the elbow.

ULNAR NERVE BLOCK, AT THE WRIST

Anatomy: The ulnar nerve lies between the distal and proximal flexor skin creases of the wrist, lateral (i.e., radial) to the flexor carpi ulnaris tendon and medial (i.e., ulnar) to the ulnar artery (**Figure 156-22B**). The innervation of the ulnar nerve is described in the previous section.

Patient positioning: Place the patient supine with their arm abducted 45° to 90°, the elbow fully extended, and the hand supinated (**Figure 156-22B**).

Landmarks: Identify the flexor carpi ulnaris tendon by flexing the patient's clenched hand against resistance. Mark the medial aspect of the flexor carpi ulnaris tendon. Identify the ulnar artery by its palpable pulsations between the proximal and distal wrist crease. Note the position of the proximal and distal wrist creases.

Needle insertion and direction: Place a skin wheal of local anesthetic solution in the quadrangle defined by the proximal flexor skin crease, the distal flexor skin crease, the lateral aspect of the flexor carpi ulnaris tendon, and medial to the ulnar artery. Insert a 25 gauge needle perpendicular to the skin wheal and slowly advance it 0.5 cm (**Figure 156-22B**). If paresthesias are elicited, withdraw the needle 2 mm and allow them to resolve. Inject 2 mL of local anesthetic solution once the paresthesias resolve. If paresthesias are not elicited, inject 3 to 5 mL of local anesthetic solution.

US-guided block: The nerve can be blocked with the aid of US.³⁹ Place the US transducer over the middle of the wrist with the marker pointing laterally (**Figure 156-22C**). The palmaris longus tendon should be visible in the middle of the wrist. Move the US transducer medially until the ulnar artery is visible. The ulnar nerve is hyper-echoic and directly medial to the ulnar artery (**Figure 156-22D**). Anesthetize the skin medial to the ulnar artery. Position the needle inferior to the short axis of the US transducer and directly over the ulnar nerve (**Figure 156-22C**). Insert and advance the needle until its tip is at the ulnar nerve. Aspirate to ensure that the needle tip is not in a blood vessel. Inject a test dose of 1 to 2 mL of local anesthetic solution. Watch the spread of local anesthetic solution around the ulnar nerve. If satisfactory, inject the remainder of the local anesthetic solution to produce the "donut sign." If the test dose is not satisfactory, reposition the needle and inject another test dose.

Remarks: This is the preferred approach to block the ulnar nerve. Blockade of the ulnar nerve at the wrist is very reliable and does not have the associated complications as at the elbow.^{10,39,40}

RADIAL NERVE BLOCK, AT THE ELBOW

Anatomy: The radial nerve and the sensory branch of the musculocutaneous nerve run together in the sulcus between the biceps and the brachioradialis muscle on the anterolateral aspect of the elbow. The radial nerve provides sensory innervation to portions of the dorsal arm and forearm, the dorsolateral half of the hand, and the dorsal proximal aspects of the thumb, index, middle, and radial half of the ring fingers (**Figure 156-20**).¹³ It provides motor innervation to the muscles on the posterior aspect of the arm, forearm, and hand.

Patient positioning: Place the patient supine with their elbow flexed 15° to 30°.

Landmarks: Palpate the tendon of the biceps muscle in the antecubital fossa. Identify the flexion skin crease of the elbow. Palpation of the biceps tendon is greatly facilitated by having the patient flex their elbow 90° then contract and relax their biceps muscle. Identify the medial and lateral condyles of the humerus. Draw a line between the humeral condyles (**Figure 156-23A**). This line should be located at the level of the antecubital crease.

Needle insertion and direction: Place a skin wheal of local anesthetic solution 2 cm lateral to the biceps tendon and 1 cm proximal to the antecubital crease (**Figure 156-23A**). Insert a 25 gauge needle through the skin wheal and perpendicular to the skin (**Figure 156-23A**). Advance the needle 1 to 2 cm. Move the transducer in a fan-like pattern until paresthesias are elicited. Withdraw the needle 1 to 2 mm and allow the paresthesias to resolve. Inject 5 to 7 mL of local anesthetic solution.

US-guided block: The nerve can be blocked with the aid of US. Position the patient with their arm abducted 45°, the elbow in full extension, and the hand supinated. Place the US transducer on the

lateral aspect of the crease of the antecubital fossa. The radial nerve is lateral to the biceps tendon and the brachial artery (**Figure 156-23B**). Anesthetize the skin over the radial nerve. Place the needle inferior to the short axis of the US transducer and directly over the radial nerve. Only the tip of the needle will be visualized in this view. Insert and advance the needle until its tip is at the radial nerve. Aspirate to ensure that the needle tip is not in a blood vessel. Inject a test dose of 1 to 2 mL of local anesthetic solution. Watch the spread of local anesthetic solution around the radial nerve. If satisfactory, inject the remainder of the local anesthetic solution to produce the "donut sign." If the test dose is not satisfactory, reposition the needle and inject another test dose.

The radial nerve can be blocked above the humeral condyle using US.^{42,43} Flex the patient's elbow 90° with the hand pronated. Once the radial nerve is found, the technique is similar to the above, only more proximal on the arm.

Remarks: Blockade of the radial nerve at the elbow is difficult, has limited applications, is painful for the patient, and often results in a large antecubital hematoma. The preferred technique is blockade at the wrist.

RADIAL NERVE BLOCK, AT THE WRIST

Anatomy: The radial nerve at the wrist consists of a trunk and terminal branches that arise in the forearm (**Figure 156-23C**). The innervation of the radial nerve is described in the previous section.

Patient positioning: Place the patient supine with their arm abducted 45°, the elbow fully extended, and the hand midway between supination and pronation (**Figure 156-23C**).

Landmarks: Identify the radial artery by its pulsation at the level of the proximal wrist crease.

Needle insertion and direction: Place a skin wheal of local anesthetic solution 1 mm lateral to the radial pulse. Insert a 25 gauge needle 1 mm lateral to the radial pulse, through the skin wheal, and perpendicular to the skin (**Figure 156-23C**). Advance the needle 0.5 cm. If paresthesias are elicited, withdraw the needle 1 to 2 mm and allow them to resolve. Inject 2 mL of local anesthetic solution. If paresthesias are not elicited, inject 3 to 5 mL of local anesthetic solution. This will anesthetize the terminal trunk of the radial nerve. Infiltrate 5 to 7 mL of local anesthetic solution at the level of the extensor wrist crease from the lateral aspect of the radius to the base of the fourth metacarpal (**Figure 156-23C**). This will anesthetize the terminal branches that arise in the forearm.

US-guided block: The nerve can be blocked with the aid of US.³⁹ Place the US transducer over the middle of the wrist with the marker pointing laterally (**Figure 156-23D**). The palmaris longus tendon should be visible in the middle of the wrist. Move the US transducer laterally until the radial artery is visualized. The radial nerve is hyper-echoic and directly lateral to the radial artery (**Figures 156-23E**). Anesthetize the skin lateral to the radial artery and directly over the radial nerve. Place the needle inferior to the short axis of the US transducer and directly over the radial nerve. Insert and advance the needle until its tip is at the radial nerve. Aspirate to ensure that the needle tip is not in a blood vessel. Inject a test dose of 1 to 2 mL of local anesthetic solution. Watch the spread of local anesthetic solution around the radial nerve. If satisfactory, inject the remainder of the local anesthetic solution to produce the "donut sign." If the test dose is not satisfactory, reposition the needle and inject another test dose.

Remarks: This is the preferred technique for blockade of the radial nerve.⁴⁰

WRIST BLOCK

Perform the wrist block by blocking the radial, ulnar, and median nerves at the wrist. The technique for each specific nerve block was discussed previously. The wrist block provides complete anesthesia

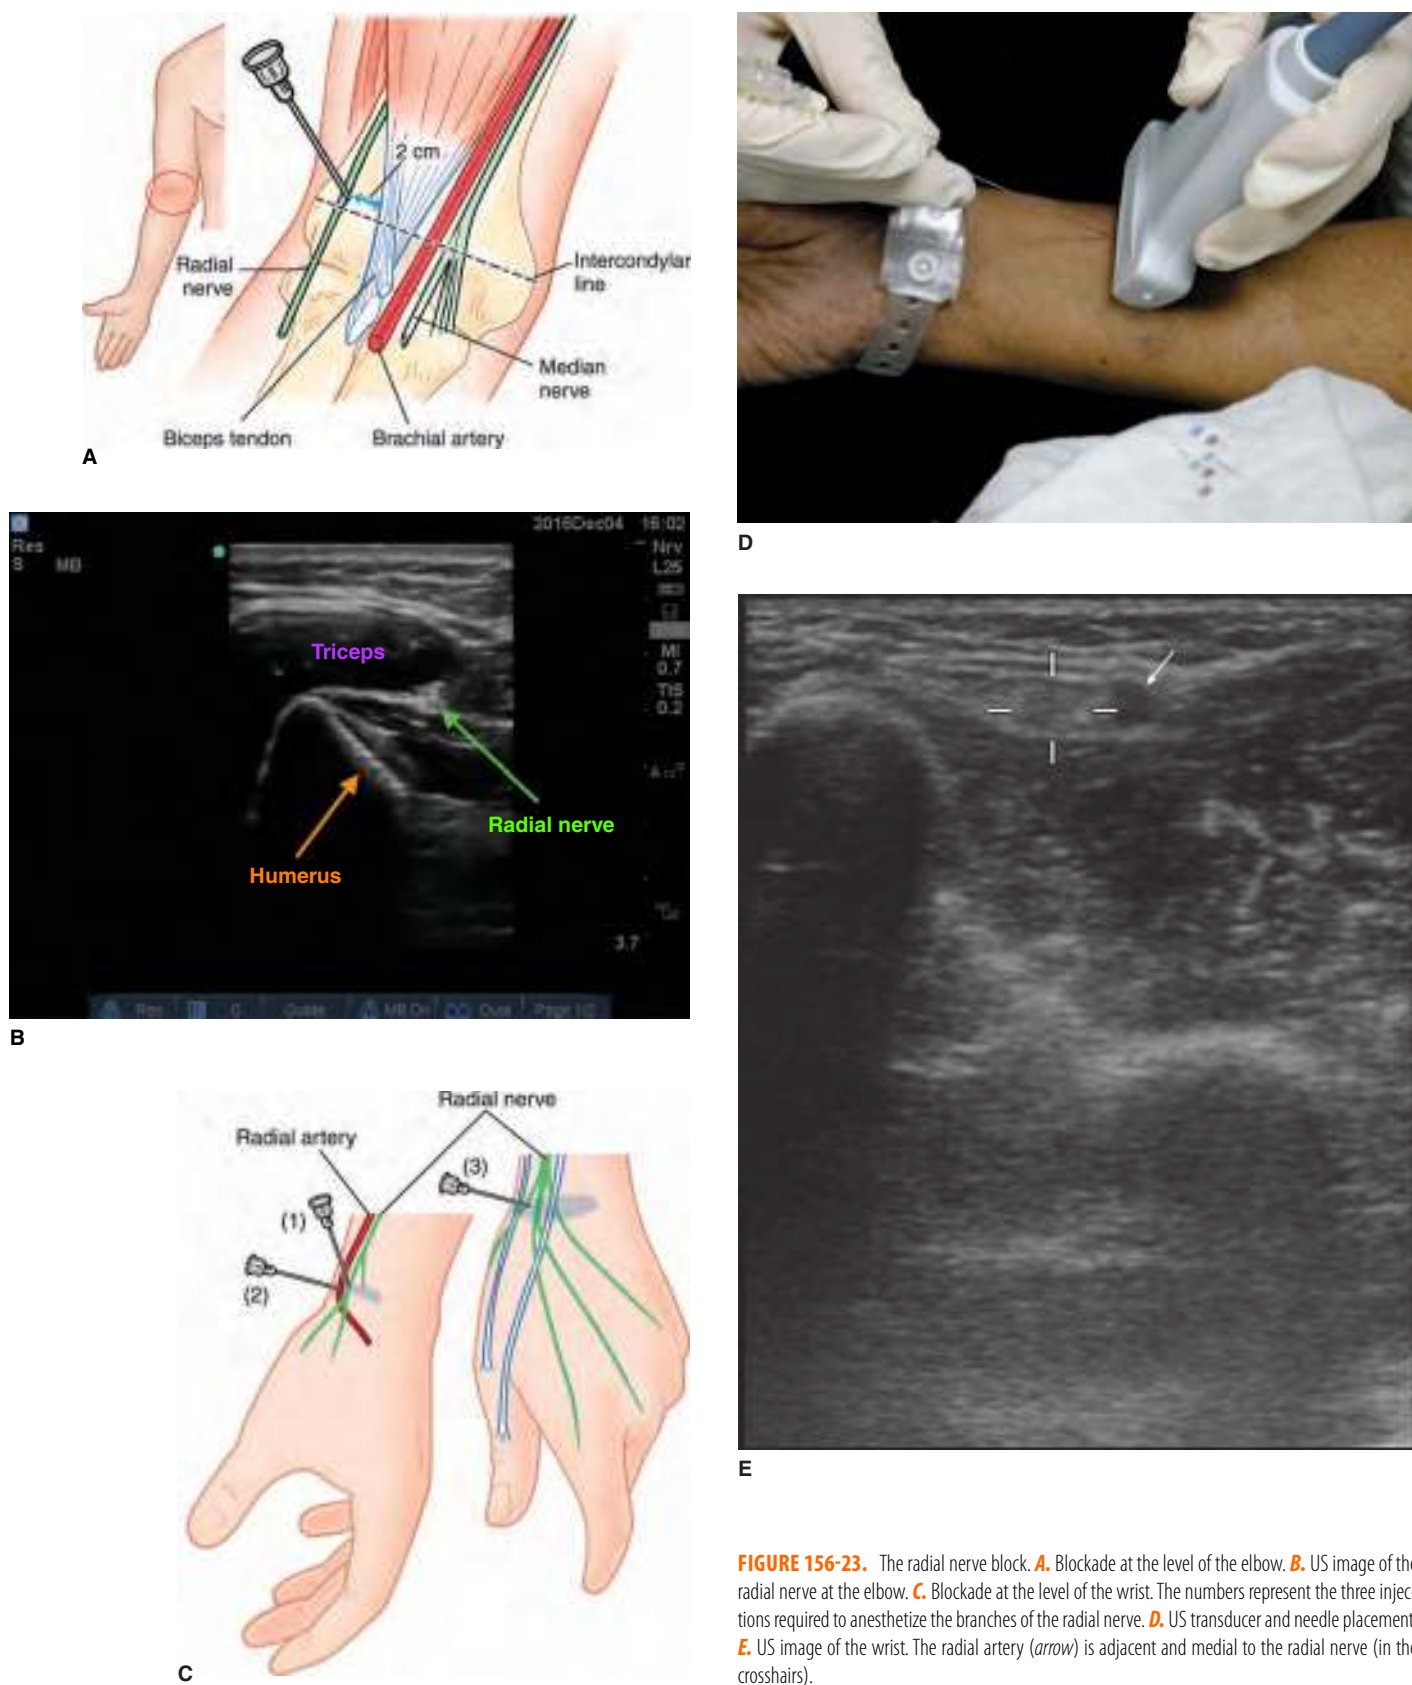

FIGURE 156-23. The radial nerve block. **A.** Blockade at the level of the elbow. **B.** US image of the radial nerve at the elbow. **C.** Blockade at the level of the wrist. The numbers represent the three injections required to anesthetize the branches of the radial nerve. **D.** US transducer and needle placement. **E.** US image of the wrist. The radial artery (arrow) is adjacent and medial to the radial nerve (in the crosshairs).

to the hand and is commonly used in hand surgery. It can be performed in the Emergency Department to provide anesthesia for burn management, foreign body removal, wound exploration, or extensive laceration repair. Wrist blockade is reliable but slow as it requires extended time to block all three nerves at the wrist.^{13,39,40,44}

INTERMETACARPAL NERVE BLOCK

Anatomy: The principal nerves supplying the finger are the palmar digital nerves which originate from the deep volar branches of the ulnar and median nerves in the region of the wrist. These nerves follow the artery along the lateral aspects of the bone and supply sensation to the volar skin, the interphalangeal joints, the distal finger, and the fingertip of all five digits.

Two dorsal and two palmar nerves supply each finger. These nerves run along the phalanges in the 2, 4, 8, and 10 o'clock positions.⁴⁵ These nerves also supply the dorsal, distal aspect of the finger including the fingertip and nail bed. The dorsal digital nerves

originate from the radial and ulnar nerves that wrap around the dorsum of the hand. They supply the nail bed of the thumb and small finger and the dorsal aspect of all five digits up to the distal interphalangeal joints. The palmar and dorsal nerves need to be blocked in the case of the thumb and fifth finger.

Patient positioning: Place the patient sitting upright or supine with their hand pronated on a bedside examination table.

Landmarks: Locate the web spaces and the metacarpal heads on each side of the finger to be blocked.

Needle insertion and direction: Insert a 25 gauge needle into the dorsal aspect of the web space on one side of the digit to be anesthetized (**Figure 156-24A**). Advance the needle approximately 0.5 cm. Inject 1 mL of local anesthetic solution. Repeat the procedure on the other side of the digit to be blocked. When blocking the second and fifth digits, a half-ring block is required on the ulnar aspect of the fifth digit and radial aspect of the second digit. When blocking the thumb, infiltrate the dorsum and sides in a half-ring manner.

FIGURE 156-24. Techniques to anesthetize the digital nerves of the fingers. **A.** Intermetacarpal nerve block through the web space. **B.** Intermetacarpal nerve block on the dorsal surface of the hand between the metacarpal heads. **C.** Intermetacarpal nerve block on the ventral surface of the hand between the metacarpal heads. **D.** The ring block. **E.** The half-ring block.

An alternative is the metacarpal head block. This technique can be used to anesthetize any of the fingers. Insert a 25 gauge needle perpendicular to the dorsum of the hand and adjacent to the metacarpal head on one side of the finger to be blocked (**Figure 156-24B**). Advance the needle 0.5 cm and inject 1 mL of local anesthetic solution. Repeat the procedure on the other side of the finger to be blocked. Some physicians prefer to perform this block on the volar aspect of the hand (**Figure 156-24C**). This technique is extremely painful and should be avoided.

Remarks: This block produces less swelling than does the ring block. Subsequently, there is less risk of vascular compromise. This is a less painful technique than the ring block. Some use the volar subcutaneous block on top of the tendon sheaths.⁴⁶ This block is effective. Some use a block that requires the needle to penetrate the flexor tendon. This cannot be recommended to penetrate the poorly vascular tendon.

DIGITAL NERVE BLOCK (RING BLOCK) OF THE FINGER

Anatomy: The anatomy and innervation of the digital nerves are described in the previous section.

Patient positioning: Place the patient sitting upright or supine with their hand pronated on a bedside examination table.

Landmarks: Locate the dorsum of the proximal phalanx to be anesthetized.

Needle insertion and direction: Insert a 25 gauge needle on the dorsal surface of the base of the proximal phalanx (**Figure 156-24D-1**). Inject 1 mL of local anesthetic solution along the dorsal surface of the finger. Remove the needle and reinsert it downward, perpendicular to the phalanx and to a depth just past the base of the phalanx (**Figure 156-24D-2**). Inject 1.0 to 1.5 mL of local anesthetic along the lateral aspect of the finger. Withdraw the needle reinsert it on the other side of the finger to be blocked and inject 1.0 to 1.5 mL of local anesthetic solution (**Figure 156-24D-3**).

An alternative is the half-ring block (**Figure 156-24E**). It is a variant of the ring block (**Figure 156-24D**). Inject 1.0 to 1.5 mL of local anesthetic solution on one side of the base of the proximal phalanx to be anesthetized. Repeat this procedure on the other side of the

finger. The injection of local anesthetic on one side of the finger is termed the half-ring block. It takes two half-ring blocks to anesthetize a finger.

Remarks: The indications for a digital block include repair of finger lacerations and amputations, reductions of fractures and dislocations, incision and drainage of infections, removal of fingernails, and relief of pain from burns. Do not inject more than 5 mL of local anesthetic solution into a digit. Using local anesthetic agents that contain epinephrine is controversial because the finger contains end arteries and may experience ischemia from the vasoconstrictive effects of epinephrine. The literature shows that local anesthesia that contains epinephrine is safe to use on the digits.⁴⁷⁻⁴⁹ The decision to use epinephrine or not use epinephrine in the digits is up to the treating physician. Some use the volar subcutaneous block on top of the tendon sheaths.⁴⁶ This block is effective. Some use a block that requires the needle to penetrate the flexor tendon. This cannot be recommended to penetrate the poorly vascular tendon.

REGIONAL ANESTHESIA TECHNIQUES FOR THE TORSO

INTERCOSTAL NERVE BLOCK

Anatomy: The intercostal nerves originate from the thoracic spinal cord and have four major branches (**Figure 156-25**). The first is the gray rami communicans to the sympathetic ganglion. The second branch is the posterior cutaneous nerve that supplies the paravertebral muscles and overlying skin. The third branch is the lateral cutaneous nerve that arises about the midaxillary line. It divides into an anterior and posterior division to supply most of the chest and the abdominal wall. The final branch is the terminal anterior cutaneous nerve. It supplies the anterior chest and abdominal wall adjacent to the midline. Each intercostal nerve travels within a neurovascular bundle behind the inferior border of each rib (**Figure 156-25B**). The intercostal nerve lies inferior to the intercostal vein and artery. The intercostal nerve may be blocked at several sites along its course. The most common site is at the angle of the rib. The technique described will be the blockade of the intercostal nerves at the angle of the rib.

FIGURE 156-25. The intercostal nerve. **A.** The anatomy of a typical thoracic spinal nerve. **B.** Cross-section through the chest wall. The intercostal nerves are contained within a neurovascular bundle that lies behind the inferior border of each rib.

Patient positioning: Place the patient prone with a pillow under the midabdomen to straighten the lumbar curve and increase the size of the intercostal spaces posteriorly.

Landmarks: The most important step is to correctly identify the anatomy of the patient. Draw a line along the vertebral spines corresponding to the levels to be anesthetized. Palpate laterally from the vertebral spines to the edge of the paraspinal muscles.

This is the location where the ribs are most superficial. This distance can vary from 6 to 8 cm from the midline in the average adult. Draw vertical lines parallel to the first line and along the edge of the paraspinal muscles (Figure 156-26A). These lines must angle slightly medially over the upper ribs to avoid the scapula. Palpate and mark the inferior edge of each rib along these two vertical lines (Figure 156-26A).

FIGURE 156-26. The intercostal nerve block. **A.** The patient is placed prone. A line is drawn along the lateral border of the paraspinal muscles. Note that the upper end is angled medially to avoid the scapula. Cross-marks are drawn to denote the inferior border of the rib and the location to perform the block. **B.** The index finger of the nondominant hand pulls the skin overlying the inferior border of the rib upward. **C.** The dominant hand is resting against the patient. The needle is inserted at a 60° angle to the skin and advanced until the rib is contacted. **D.** The fingers of the nondominant hand grasp and stabilize the needle. **E.** The needle is "walked" off the inferior border of the rib. **F.** The needle is advanced 3 mm so that the tip is within the neurovascular bundle. **G.** Inject 1 to 2 mL of local anesthetic solution while maintaining the needle in a stable position with the dominant hand.

Needle insertion and direction: This procedure requires the utmost of care to prevent inducing a pneumothorax. Inject local anesthetic solution to make a skin wheal at the intersection of the horizontal lines with the vertical paraspinal muscle lines. Use the index finger of the nondominant hand to pull the skin at the lower edge of the rib up onto the rib (**Figure 156-26B**). Grasp the syringe in the dominant hand. Insert the 25 gauge needle at a 60° angle along the tip of the nondominant index finger while the dominant hand is resting on the patient's back (**Figure 156-26C**). Advance the needle until the rib is contacted (**Figure 156-26C, inset**).

Reposition the nondominant hand so that it is resting against the patient's back and holding the needle between the thumb, index, and middle fingers (**Figure 156-26D**). Use the nondominant hand to slowly and carefully "walk" the needle off the inferior rib margin (**Figure 156-26E**). Advance the needle 3 mm with the nondominant hand (**Figure 156-26F**). **It is imperative that the needle not be advanced more than 3 mm after it is "walked" off the inferior border of the rib to prevent an iatrogenic pneumothorax. Aspirate to ensure that the tip of the needle is not within a blood vessel or the lung.** Inject 1 to 2 mL of local anesthetic solution (**Figure 156-26G**). Remove the needle and repeat the procedure at the other desired interspaces.

Remarks: Local anesthetic solution for intercostal blocks should contain 1:200,000 or less of epinephrine. The nerve can be blocked with the aid of US.⁵⁰ The only advantage is visualization of the underlying lung may prevent an iatrogenic pneumothorax. **Obtain a postprocedural upright chest radiograph to ensure that the patient does not have an iatrogenic pneumothorax.**⁵¹

PENILE BLOCK

The penis may be anesthetized for the purposes of circumcision, laceration repair, foreign body removal, zipper entrapment, or to perform the release of a phimosis or paraphimosis. The dorsal nerves of the penis provide sensory innervation to the penis. They emerge from under the pubis just lateral to the symphysis and course along the dorsal surface of the penis. These nerves are located approximately 0.5 cm from the dorsal penile midline. These nerves are blocked at the base of the penis. Refer to Chapter 177 for the complete details of the penile block.

REGIONAL ANESTHESIA TECHNIQUES FOR THE LOWER EXTREMITY

The sensory innervation of the lower extremity is illustrated in **Figure 156-27**. Note that the nerves provide patches of innervation rather than stripes of innervation beginning at the torso and extending to the foot.

FEMORAL NERVE BLOCK

Anatomy: The femoral nerve is formed from the lumbar plexus. It travels in the pelvis between the iliacus and psoas major muscles. It enters the thigh below the inguinal ligament, midway between the anterior superior iliac spine and the pubic tubercle (**Figure 156-28A**). The femoral nerve lies anterior to the iliopsoas muscle and lateral to the femoral artery in the proximal thigh (**Figure 156-28B**). The femoral nerve has both sensory and motor components. It provides motor innervation to the anterior thigh muscles. It provides sensory innervation for the anterior thigh, anteromedial thigh, medial thigh, medial leg, and medial border of the foot (**Figure 156-27**).

Patient positioning: Place the patient supine with their hip and knee extended and the leg slightly externally rotated.

Landmarks: Identify the anterior superior iliac spine and the pubic tubercle by palpation. Connect these landmarks with a

straight line to roughly approximate the position of the inguinal ligament. Identify the femoral artery by its palpable pulse 1 to 2 cm below the midpoint of the inguinal ligament.

Needle insertion and direction: Place a skin wheal of local anesthetic solution just lateral to the femoral artery pulse. Insert a 25 gauge needle through the skin wheal and perpendicular to the skin (**Figure 156-28B**). Slowly advance the needle while remaining perpendicular to the skin. The femoral nerve is identified once paresthesias are elicited. Withdraw the needle 2 mm and allow the paresthesias to resolve. Inject 15 to 20 mL of local anesthetic solution.

US-guided block: The nerve can be blocked with the aid of US.⁵²⁻⁵⁵ Place the US transducer along the inguinal crease, midway between the anterior superior iliac spine and the pubic tubercle (**Figure 156-28C**). Identify the femoral artery and femoral vein. The femoral nerve is hyperechoic and located 0.5 to 1 cm lateral and posterior to the common femoral artery (**Figure 156-28D**). Apply pressure with the US transducer to distinguish the compressible femoral vein from the incompressible femoral artery. Use color Doppler to confirm the location of the femoral artery and any branches or take-offs. Place the needle lateral to the long axis of the US transducer (**Figure 156-28C**). Slowly insert and advance the needle. Visualize the entire length of the needle as it is inserted and approaches the femoral nerve. Continue to advance the needle and penetrate the fascia lata and fascia iliaca so that the tip of the needle is adjacent to the femoral nerve. Aspirate to ensure that the needle tip is not in a blood vessel. Inject a test dose of 1 to 2 mL of local anesthetic solution. Watch the spread of local anesthetic solution around the femoral nerve. If satisfactory, inject the remainder of the local anesthetic solution to produce the "donut sign." If the test dose is not satisfactory, reposition the needle and inject another test dose.

Remarks: The femoral nerve is contained within a fibrous sheath that is separate from the other contents (i.e., the femoral artery and vein) of the femoral triangle (**Figure 156-28B**). **Paresthesias must be elicited to confirm the proper position of the tip of the needle before injecting the local anesthetic solution if using the landmark technique.** Deposition of the local anesthetic solution outside of the fibrous sheath will not result in any anesthesia except in the area of the injection.

SAPHENOUS NERVE BLOCK, AT THE KNEE

Anatomy: The saphenous nerve is the terminal branch of the femoral nerve. It travels across the anterior thigh in a medial direction to become superficial at the medial knee after emerging between the tendons of the gracilis and sartorius muscles (**Figure 156-29A**). It follows the great saphenous vein from above the knee to below the medial malleolus (**Figure 156-29B**). It provides sensory innervation to the anteromedial leg, medial leg, posteromedial leg, and medial border of the foot to the ball of the great toe (**Figure 156-27**). It has no motor component.

Patient positioning: Place the patient supine with their ankle supported on a pillow or blanket, the knee extended, and the leg externally rotated.

Landmarks: Identify the femoral condyle above the knee or the tibial condyle below the knee by palpation.

Needle insertion and direction: Place a skin wheal of local anesthetic solution over the posteromedial aspect of either condyle (i.e., femoral or tibial). Insert a 25 gauge needle through the skin wheal. Infiltrate 7 to 10 mL of local anesthetic solution subcutaneously in a transverse line from the posteromedial to the anteromedial aspect of either condyle (**Figure 156-29C**).

US-guided block: The nerve can be blocked with the aid of US. Identify the femoral artery and femoral nerve at the inguinal crease (see femoral nerve block). Move the US transducer inferiorly and

FIGURE 156-27. The sensory distribution of the cutaneous nerves of the lower extremity.

medially keeping the femoral artery in the center of the screen. At the mid-thigh, the saphenous nerve travels with the femoral artery and the nerve to the vastus medialis muscle. These structures lie posterior to the sartorius muscle and medial to the vastus medialis muscle (**Figure 156-29D**). Continue to move the transducer inferiorly and medially until the transducer is at the distal third of the thigh. Use color Doppler to confirm the location of the femoral artery and any branches or take-offs. The saphenous nerve is medial to the femoral artery and posterior (i.e., deep) to the sartorius muscle (**Figure 156-29D**). The small saphenous nerve may not be visualized by US at this level. The target is the fascial plane between the sartorius and vastus medialis muscle.

Place the needle lateral to the long axis of the US transducer. Insert and advance the needle. Visualize the entire length of the needle as it is inserted and approaches the fascial plane between the sartorius and vastus medialis muscles. Aspirate to ensure the needle tip is not in a blood vessel. Inject a test dose of 1 to 2 mL of local anesthetic solution. Watch the test dose spread the local anesthetic solution

around the 12 o'clock to 2 o'clock position of the femoral artery. If it is satisfactory, inject another 5 to 10 mL of the local anesthetic solution. If the test dose is not satisfactory, reposition the needle and inject another test dose.

Remarks: The saphenous nerve may be blocked at the ankle if anesthesia of the medial leg is not required.

SAPHENOUS NERVE BLOCK, AT THE ANKLE

Anatomy: The saphenous nerve divides into numerous terminal branches in the distal leg. These terminal branches travel across the anteromedial ankle (**Figure 156-29B**) to innervate the anteromedial aspect of the ankle and foot (**Figure 156-27**).

Patient positioning: Place the patient supine with their ankle supported on a pillow or blanket, the knee extended, and the leg externally rotated.

Landmarks: Identify the anterior border of the medial malleolus and the great saphenous vein by palpation.

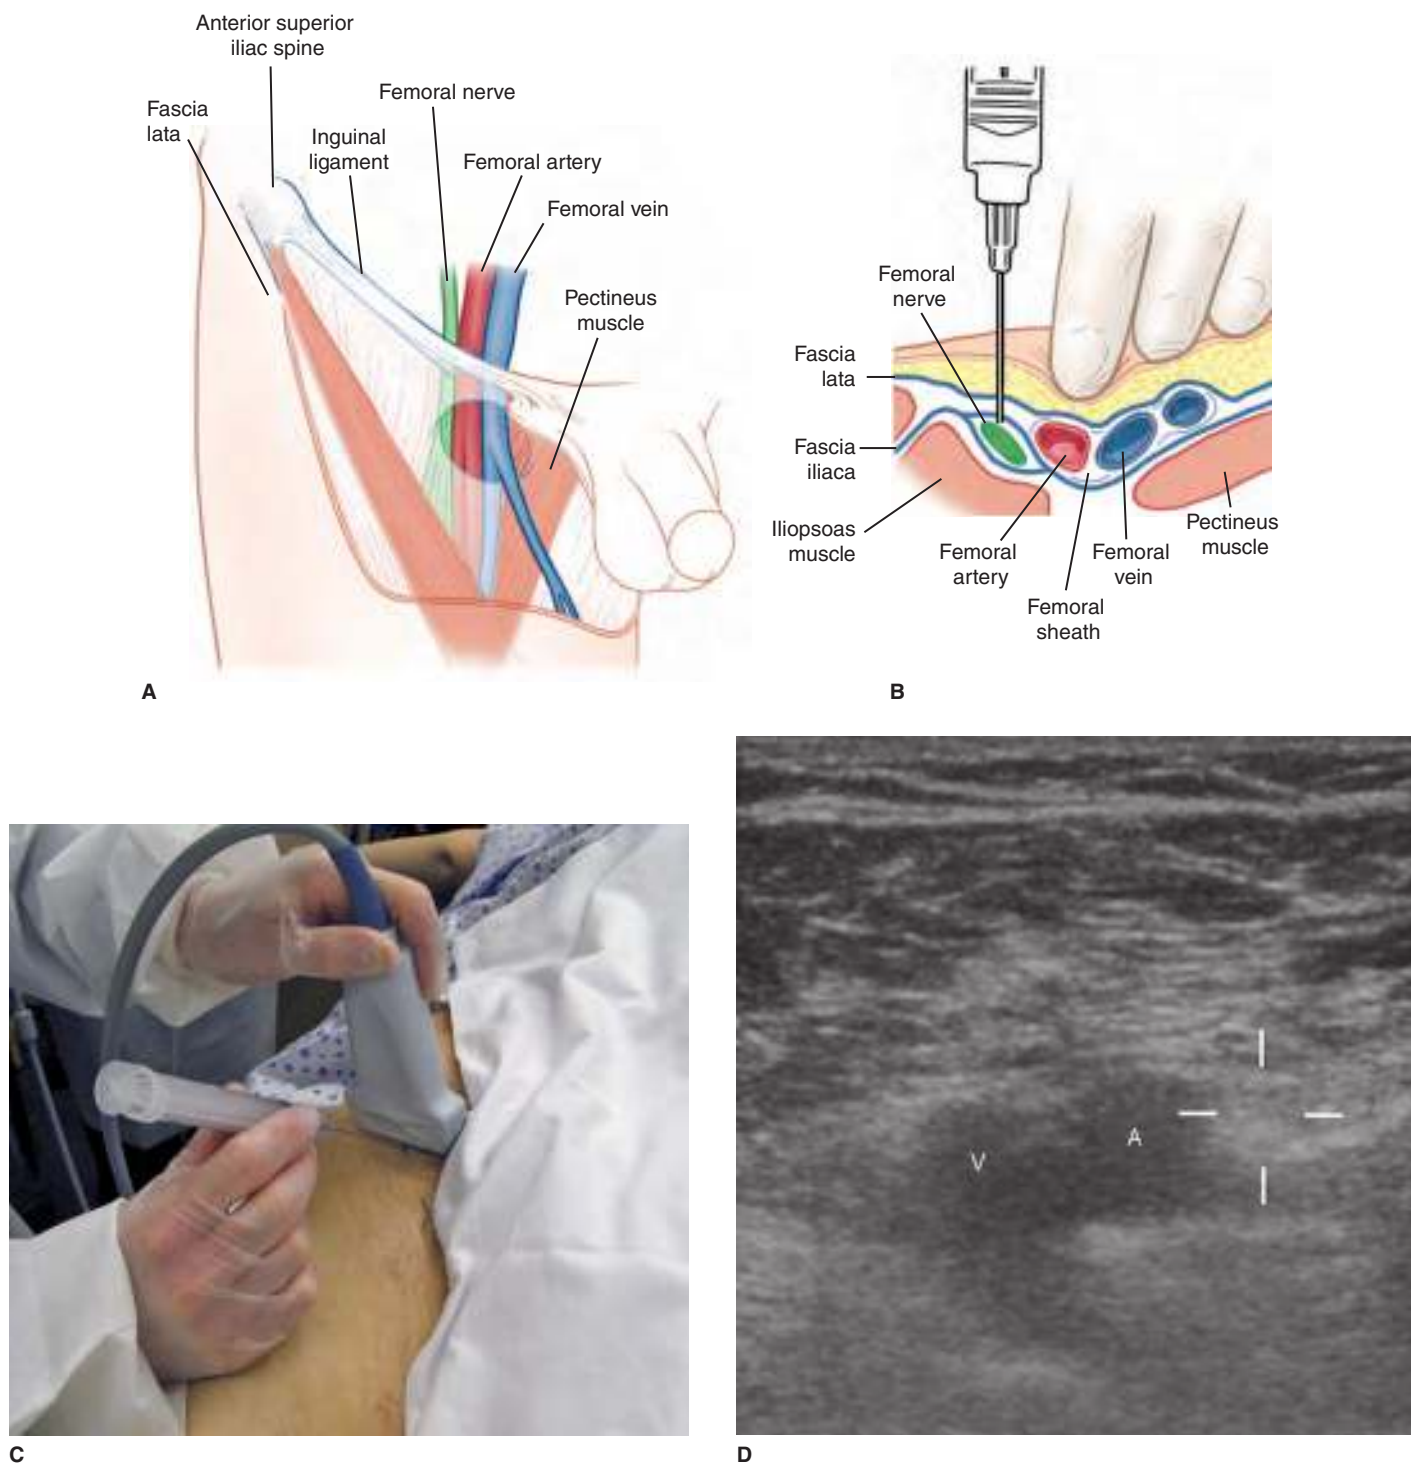

FIGURE 156-28. The femoral nerve block. **A.** The anatomy of the inguinal region. **B.** Blockade of the femoral nerve. **C.** US transducer and needle placement. **D.** US image of the femoral neurovascular bundle. The femoral nerve is located within the crosshairs (A, femoral artery; V, femoral vein).

Needle insertion and direction: Place a skin wheal of local anesthetic 1.5 cm superior and anterior to the medial malleolus. Insert a 25 gauge needle through the skin wheal. Infiltrate 3 to 5 mL of local anesthetic solution subcutaneously in a fan-like pattern around the great saphenous vein.

US-guided block: The nerve can be blocked with the aid of US. Identify the great saphenous vein anterior to the medial malleolus. Use color Doppler to confirm the location of the great saphenous vein. The saphenous nerve is adjacent to the great saphenous vein. The small saphenous nerve may not be visualized by US at this level.

Place the needle lateral to the long axis of the US transducer. Insert the needle until its tip is adjacent to the great saphenous vein. Aspirate to ensure the needle tip is not in a blood vessel. Inject a test dose of 1 to 2 mL of local anesthetic solution. Watch the test dose spread the local anesthetic solution around the great saphenous vein. If it is satisfactory, inject another 2 to 3 mL of the local anesthetic solution. If the test dose is not satisfactory, reposition the needle and inject another test dose.

Remarks: Alternatively, infiltrate 5 to 7 mL of local anesthetic solution subcutaneously in a transverse line from the anterior

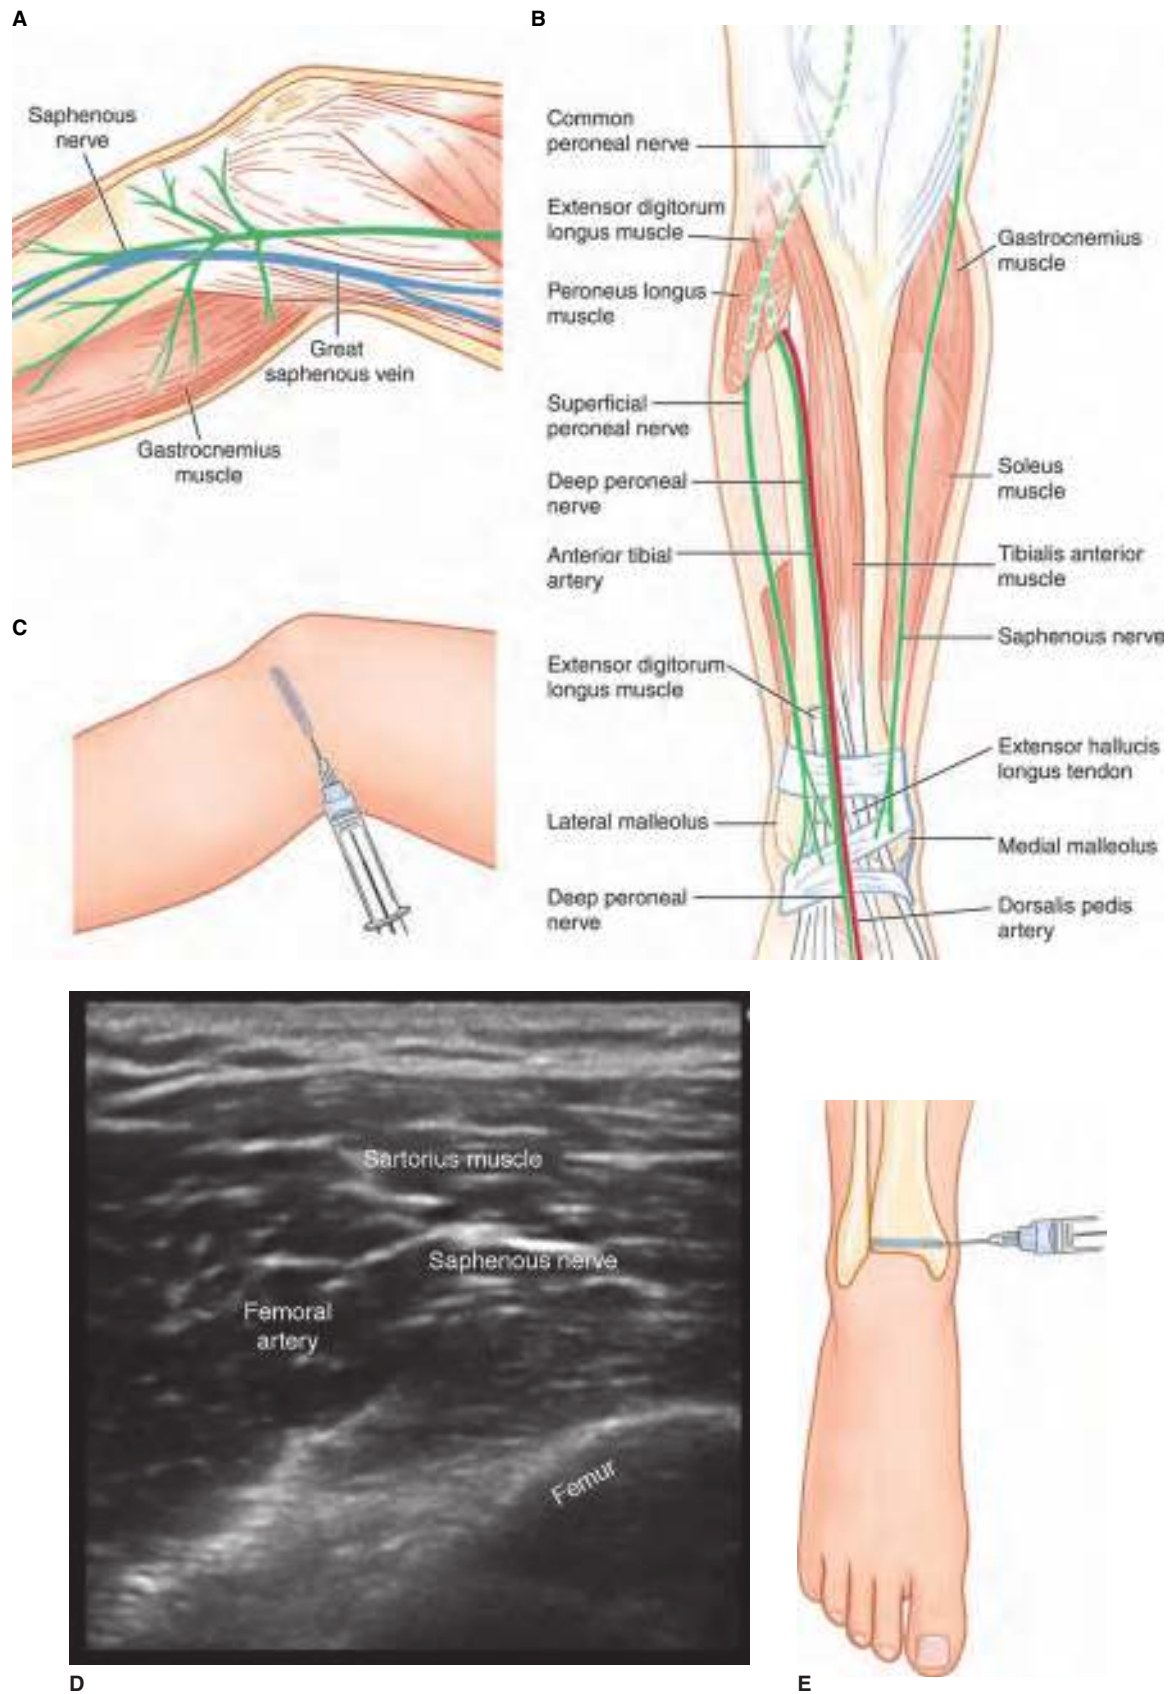

FIGURE 156-29. The saphenous nerve block. **A.** The course of the saphenous nerve at the medial knee. **B.** The course of the saphenous nerve in the leg. **C.** Blockade at the level of the knee. **D.** US image of the saphenous nerve in the distal thigh. **E.** Blockade at the level of the ankle.

border of the medial malleolus to the anterior border of the anterior tibial ridge (**Figure 156-29E**).

LATERAL FEMORAL CUTANEOUS NERVE BLOCK

Anatomy: The lateral femoral cutaneous nerve enters the thigh through or below the inguinal ligament, 1 to 2 cm medial to the anterior superior iliac spine (**Figure 156-30A**). It crosses through or over the sartorius muscle to lie on its anterior surface and deep to the fascia lata. This nerve provides sensory innervation to the anterolateral and lateral thigh (**Figure 156-27**). It has no motor components.

Patient positioning: Place the patient supine with their hip and knee extended.

Landmarks: Identify the anterior superior iliac spine by palpation.

Needle insertion and direction: Place a skin wheal of local anesthetic solution 2 to 3 cm inferior and 2 to 3 cm medial to the anterior superior iliac spine. Insert a 25 gauge needle perpendicular to the skin wheal. Advance the needle through the fascia lata. A “pop” will be felt as the needle traverses through the fascia lata. Infiltrate 10 mL of local anesthetic solution subcutaneously in a superior to inferior fan-like pattern.

A second approach begins with making the same skin wheal. Insert the needle through the skin wheal directed laterally and superiorly. Advance the needle to contact the iliac bone just medial and inferior to the anterior superior iliac spine. Infiltrate 10 mL of local anesthetic solution subcutaneously in a fan-like pattern about the iliac bone.

US-guided block: The nerve can be blocked with the aid of US. Place the US transducer along the inguinal ligament and just medial to the anterior superior iliac spine. Move the US transducer medially and inferiorly. Identify the fascia lata, fascia iliaca, and sartorius muscle (from superficial to deep, respectively). It may be difficult to identify the small lateral femoral cutaneous nerve between the fascia lata and fascia iliaca just above the sartorius muscle.

Place a skin wheal of local anesthetic solution. Place the needle lateral to the long axis of the US transducer. Insert and advance the needle. Visualize the entire length of the needle as it is inserted and approaches the lateral femoral cutaneous nerve. If the nerve cannot be identified, direct the needle immediately medial and inferior to the anterior superior iliac spine near the sartorius muscle insertion site. Advance the needle tip between the fascia lata and fascia iliaca. Aspirate to ensure the needle tip is not in a blood vessel. Inject a test dose of 1 to 2 mL of local anesthetic solution. Watch the test dose spread in the fascial plane of fascia lata and fascia iliaca. If it is satisfactory, inject another 5 to 10 mL of the local anesthetic solution. If the test dose is not satisfactory, reposition the needle and inject another test dose.

Remarks: A third, or alternative, approach is often used (**Figure 156-30B**). Place a skin wheal of local anesthetic solution just medial to the anterior superior iliac spine. Insert the needle through the skin wheal and perpendicular to the skin. Advance the needle until a “pop” is felt as the needle transverses the aponeurosis of the external oblique muscle. Continue to slowly advance the needle until a second “pop” is felt as the needle transverses through the internal oblique muscle and underlying iliac fascia. Inject 5 to 10 mL of local anesthetic solution. This approach blocks the nerve in its canal as it begins to pass under the inguinal ligament.

OBTURATOR NERVE BLOCK

Anatomy: The obturator nerve originates from the lumbar plexus. It passes through the pelvis and obturator canal to exit the obturator foramen into the thigh with its accompanying artery and vein (**Figure 156-31A**). It divides within the obturator canal into anterior and posterior branches. The anterior branch provides the sensory innervation to the hip and motor innervation to the anterior adductor muscles. There may also be a small and inconsistent area of

FIGURE 156-30. The lateral femoral cutaneous nerve block. **A.** The course of the lateral femoral cutaneous nerve. **B.** The third or alternative approach to blockade of the nerve.

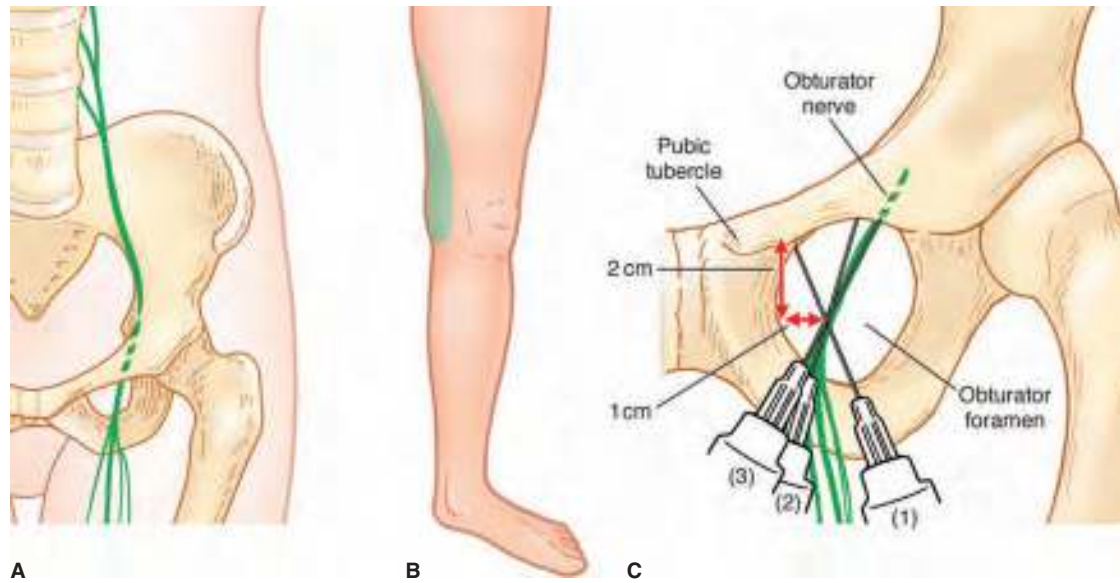

FIGURE 156-31. The obturator nerve block. **A.** The course of the obturator nerve. **B.** The sensory distribution of the obturator nerve. **C.** Blockade of the obturator nerve.

cutaneous innervation over the medial thigh (Figures 156-27 and 156-31B). The posterior branch provides motor innervation to the deep adductor muscles and sensory innervation to the knee joint.

Patient positioning: Place the patient supine with their hip and knee extended. Abduct the hip 10° to 20°.

Landmarks: Identify the pubic tubercle by palpation.

Needle insertion and direction: Place a skin wheal of anesthetic solution 1.5 cm inferior and 1.5 cm lateral to the pubic tubercle. Insert a 7 to 10 cm, 22 to 25 gauge spinal needle directed medially through the skin wheal. Advance the needle until it contacts the horizontal ramus of the pubic bone (Figure 156-31C-1). Withdraw the needle slightly (2 to 3 mm) and redirect it 45° superiorly. Advance the needle to identify the superior bony portion of the obturator canal (Figure 156-31C-2). Withdraw the needle slightly (2 to 3 mm). Redirect the needle slightly laterally and inferiorly towards the obturator canal. Advance the needle 2 to 3 cm (Figure 156-31C-3). Inject 10 to 15 mL of local anesthetic solution.

US-guided block: The nerve can be blocked with the aid of US. Place the US transducer along the medial third of the inguinal crease. Scan distally from the inguinal crease and identify the adductor longus, adductor brevis, and adductor magnus muscles (from superficial to deep, respectively). The obturator nerve divides into two branches distal to the inguinal crease, the anterior and posterior branches. The anterior branch lies in the fascial plane between the adductor longus and adductor brevis. The posterior branch lies in the fascial plane between the adductor brevis and adductor magnus. Both branches are small nerves and may or may not be identified under US.

Place a skin wheal of local anesthetic solution. Place the needle lateral to the long axis of the US transducer. Insert the needle in the plane of the long axis of the US beam. To block the anterior branch of the obturator nerve, visualize the entire length of the needle as it is inserted and approaches the fascial plane between the adductor longus and brevis. To block the posterior branch, insert the needle into the fascial plane between the adductor brevis and magnus. Once the needle tip is in between the fascial planes, aspirate to ensure the needle tip is not in a blood vessel. Inject a test dose of 1 to 2 mL of local anesthetic solution. Watch the test dose spread the two fascial planes. If it is satisfactory, inject another 10 to 15 mL of the local anesthetic solution. If the test dose is not satisfactory, reposition the needle and inject another test dose.

Remarks: The purpose of this block is to provide analgesia for an acute hip fracture when the administration of intravenous analgesics is contraindicated. The technique requires significant experience and is time-consuming. **The obturator nerve must be anesthetized within the bony canal to prevent the needle from perforating the bladder or vagina.** This block is rarely performed in the Emergency Department but its use is increasing as bedside US use and its applications are increasing.

SCIATIC NERVE BLOCK, CLASSIC OR POSTERIOR APPROACH

Anatomy: The sciatic nerve arises from the lumbosacral plexus and leaves the pelvis through the greater sciatic foramen inferior to the piriformis muscle (Figure 156-32). It is located midway between the ischial tuberosity and the greater trochanter of the femur. The nerve is superficial and accessible at the inferior border of the gluteus maximus muscle. The sciatic nerve provides the motor innervation to the muscles of the posterior thigh, leg, and foot. It provides sensory innervation to the posterior thigh, anterolateral leg, posterolateral leg, lateral leg, and almost the entire foot. There are four techniques for sciatic nerve blockade. These approaches were developed to allow sciatic nerve blockade from a variety of positions, thus eliminating positioning problems that are encountered in the elderly, the infirm, and the trauma patient.

Patient positioning: Place the patient on the side opposite that to be blocked. Flex the hip and knee of the upper leg until the heel is over the dependent knee (Figure 156-33A).

Landmarks: Identification of the anatomic landmarks is the key to success (Figure 156-33B). Identify the greater trochanter of the femur and the posterior superior iliac spine by palpation. Connect these two landmarks with a straight line. Identify the midpoint of this line and draw a perpendicular bisector downward for 3 cm. This point represents the site of local anesthetic injection. Verify the position for injection with a second line. Reidentify the greater trochanter of the femur and the sacral cornu. Draw a line starting from 1.5 cm below the sacral cornu to the greater trochanter. This line should cross the end of the perpendicular bisector and be directly over the sciatic nerve (Figure 156-33B).

Needle insertion and direction: Place a skin wheal of local anesthetic solution at the identified injection site. Insert a 22 gauge

FIGURE 156-32. The course of the sciatic nerve.

needle perpendicular to the skin wheal. Advance the needle until paresthesias are elicited. **If paresthesias are not elicited, redirect the needle to find the sciatic nerve. The nerve must be located prior to infiltration with the local anesthetic solution to achieve proper anesthesia.** Withdraw the needle 2 mm and allow the paresthesias to resolve. Inject 20 to 30 mL of local anesthetic solution.

US-guided block: The nerve can be blocked with the aid of US.⁵³ Place the US transducer over the previously identified intersection point (**Figure 156-33B**). Place the long axis of the US transducer

along the line between the greater trochanter and the sacral hiatus. Identify the ischial bone as a hyperechoic line with a bony shadow underneath and medial to the sciatic nerve. Identify the gluteus maximus muscle superficial (i.e., posterior) to the sciatic nerve. The sciatic nerve appears wide and flat between the gluteus maximus muscle and the ischial bone (**Figure 156-33C**). Scan cephalad and caudad to obtain the best view of the sciatic nerve.

Place a skin wheal of local anesthetic solution. Place the needle lateral to the long axis of the US transducer. Insert the needle in the

FIGURE 156-33. The classic or posterior approach to the sciatic nerve block. **A.** Patient positioning. **B.** Identification of the landmarks required to perform the block. **C.** US image of the sciatic nerve underneath the gluteus maximus muscle.

plane of the long axis of the US beam. Advance the needle toward the sciatic nerve. Stop advancing the needle when its tip is adjacent to the sciatic nerve. Aspirate to ensure that the needle tip is not in a blood vessel. Inject a test dose of 1 to 2 mL of local anesthetic solution. Watch the spread of local anesthetic solution around the sciatic nerve. If satisfactory, inject 15 to 20 mL of local anesthetic solution to produce the “donut sign.” If the test dose is not satisfactory, reposition the needle and inject another test dose.

Remarks: Blockade of the sciatic nerve can be used for fracture reduction, extensive laceration repair, incision and drainage of abscesses, wound exploration, or anesthesia from burns or trauma. The posterior approach is the most commonly performed technique.⁵⁶

SCIATIC NERVE BLOCK, ANTERIOR APPROACH

Anatomy: The anatomy and innervation of the sciatic nerve are described in the previous section. This approach can be used for patients who cannot be turned onto their side.

Patient positioning: Place the patient supine with their hip and knee extended.

Landmarks: Identification of the anatomic landmarks is the key to success (Figure 156-34A). Identify the anterior superior iliac spine and the pubic tubercle by palpation. Connect these points with a straight line (Figure 156-34A, Line 1). This line represents the location of the inguinal ligament. Trisect the inguinal ligament line into three equal parts. Draw a line perpendicular from the junction of the medial and middle thirds (Figure 156-34A, Line 2). Identify the tuberosity of the greater trochanter by palpation. Draw a line from the tuberosity medially across the anterior thigh and parallel to the line representing the inguinal ligament (Figure 156-34A, Line 3). The point of intersection of this line (Figure 156-34A, Line 3) with the perpendicular line from the inguinal ligament (Figure 156-34A, Line 2) represents the point of injection.

Needle insertion and direction: Place a skin wheal of local anesthetic solution at the identified injection site. Insert a 10 to 15 cm long, 22 gauge needle perpendicular to the skin and aimed slightly lateral. Advance the needle until the femur is contacted (Figure 156-34B-1).

Withdraw the needle 1 cm and redirect it medially. Advance the needle 5 cm past the location where the bone was found (i.e., 6 cm; Figure 156-34B-2). The needle should be within the neurovascular bundle containing the sciatic nerve. The average distance from the surface of the femur to the neurovascular bundle is 4.5 to 6.0 cm in adults. **Inject a small test dose of local anesthetic solution to determine the ease of injection. The tip of the needle is within muscle or a fascial plane if significant resistance is encountered.** Advance the needle until resistance to injection is at a minimum. Eliciting paresthesias is extremely helpful in identifying the correct location of the needle. If paresthesias are elicited, withdraw the needle 2 mm and allow them to resolve. Inject 15 to 30 mL of local anesthetic solution.

Remarks: The posterior femoral cutaneous nerve, which accompanies the sciatic nerve, may sometimes be missed with this approach. This technique is extremely painful and not often performed.

SCIATIC NERVE BLOCK, LITHOTOMY APPROACH

Anatomy: The anatomy and innervation of the sciatic nerve are described in the previous section. The sciatic nerve lies anterior to the gluteus maximus muscle when the patient is in the lithotomy position. The nerve is more superficial in this position than in the other approaches.

Patient positioning: Place the patient supine. Maximally flex the hip and knee of the extremity to be anesthetized. Use a bed or examination table with foot stirrups if available and not contraindicated.

Landmarks: Identify the ischial tuberosity and the greater trochanter of the femur by palpation. Connect these landmarks with a straight line. Identify the midpoint of this line.

Needle insertion and direction: Place a skin wheal of local anesthetic solution at the midpoint of the line from the ischial tuberosity to the greater trochanter. Insert a 10 to 15 cm long, 22 gauge spinal needle perpendicular to the skin wheal. Slowly advance the needle until paresthesias are elicited. Withdraw the needle 2 mm and allow the paresthesias to resolve. Inject 20 to 25 mL of local anesthetic solution.

US-guided block: The nerve can be blocked with the aid of US. Place the US transducer over the midpoint of the line connecting

FIGURE 156-34. The anterior approach to the sciatic nerve block. **A.** Identification of the landmarks. **B.** Blockade of the sciatic nerve.

the greater trochanter and the ischial tuberosity with the long axis of the US transducer along the line between the bony landmarks. Identify the gluteus maximus muscle superior (i.e., posterior) to the sciatic nerve. Identify the sciatic nerve between the greater trochanter and the ischial tuberosity, anterior (i.e., deep) to the gluteus maximus muscle. Scan cephalad and caudad to obtain the best view of the sciatic nerve.

Place a skin wheal of local anesthetic solution. Place the needle lateral to the long axis of the US transducer. Insert the needle in the plane of the long axis of the US beam. Advance the needle toward the sciatic nerve. Stop advancing the needle when its tip is adjacent to the sciatic nerve. Aspirate to ensure that the needle tip is not in a blood vessel. Inject a test dose of 1 to 2 mL of local anesthetic solution. Watch the spread of local anesthetic solution around the sciatic nerve. If satisfactory, inject 15 to 20 mL of local anesthetic solution to produce the “donut sign.” If the test dose is not satisfactory, reposition the needle and inject another test dose.

Remarks: This approach is more difficult to master than the previous two techniques. It is time-consuming and requires locating the sciatic nerve by eliciting paresthesias prior to injecting the local anesthetic solution.

SCIATIC NERVE BLOCK, LATERAL APPROACH

The lateral approach will not be described. This approach requires considerable experience, a nerve stimulator, and does not provide any advantage over the other approaches.

POPLITEAL FOSSA NERVE BLOCK, ANATOMIC OR POSTERIOR APPROACH

Anatomy: The popliteal fossa is a diamond-shaped area on the posterior aspect of the knee (**Figure 156-35**). Its boundaries are the long head of the biceps femoris muscle superolaterally, the semimembranosus and semitendinosus muscles superomedially, and the medial and lateral heads of the gastrocnemius muscle inferiorly. This space contains the tibial and common peroneal nerves, the popliteal artery and vein, and loose fatty connective tissue (**Figure 156-35A**). The nerves are superficial to the arteries and veins, midway between the skin and the posterior surface of the femur. The average distance between the skin and the nerves is 1.5 to 2.0 cm in adults. These nerves are responsible for the motor innervation of all the muscles below the knee. They also provide sensory innervation to the entire leg below the knee except the area innervated by the saphenous nerve.

Patient positioning: Place the patient prone with a pillow or blanket under their ankle to position the knee in slight flexion (10° to 20°).

Landmarks: Identify the borders of the popliteal fossa. Divide the fossa into a superior and inferior triangle with a line drawn medial to lateral across the skin fold or crease (**Figure 156-35B**). Draw a line from the apex to the base of the superior triangle, making two smaller and equal triangles (**Figure 156-35B**). Identify the spot 5 cm superior and 1 cm lateral to the midline of the upper triangle. This spot represents the landmark for needle insertion.

Needle insertion and direction: Place a skin wheal of local anesthetic solution 5 cm superior and 1 cm lateral to the midline of the upper triangle (**Figure 156-35B**). Insert a 25 gauge needle through the skin wheal, directed superiorly, and at a 45° to 60° angle to the skin surface. Advance the needle anteriorly and superiorly until paresthesias are elicited. Withdraw the needle 2 mm and allow the paresthesias to resolve. Infiltrate 35 to 45 mL of local anesthetic solution.

US-guided block: The nerve can be blocked with the aid of US.^{33,57} Place the US transducer 10 cm proximal to the skin crease. The sciatic nerve lies between the biceps femoris muscle laterally and the semimembranosus and semitendinosus muscles medially

(**Figure 156-35C**). Scan cephalad and caudad to obtain the best view of the sciatic nerve and to identify where the sciatic nerve branches into the tibial and the common peroneal nerves.

Place a skin wheal of local anesthetic solution. Place the needle lateral to the long axis of the US transducer. Insert the needle in the plane of the long axis of the US beam. Advance the needle toward the sciatic nerve. Stop advancing the needle when its tip is adjacent to the sciatic nerve. Aspirate to ensure that the needle tip is not in a blood vessel. Inject a test dose of 1 to 2 mL of local anesthetic solution. Watch the spread of local anesthetic solution around the sciatic nerve. If satisfactory, inject 10 to 15 mL of local anesthetic solution to produce the “donut sign.” If the test dose is not satisfactory, reposition the needle and inject another test dose.

Remarks: This block is difficult to use in patients who cannot lie in the prone position. This includes pregnant patients, the morbidly obese, spinal injury patients, hemodynamically unstable patients, and those on mechanical ventilation.⁵⁶

COMMON PERONEAL NERVE BLOCK

Anatomy: The common peroneal nerve originates in the popliteal fossa as one of the terminal branches of the sciatic nerve (**Figure 156-36A**). It courses posterolaterally around the neck of the fibula where it can be palpated. It provides motor innervation to the peroneal muscles and the muscles of the anterior leg and foot. It provides sensory innervation to the anterior leg, dorsum of the foot and toes, and the medial great toe (**Figure 156-27**).

Patient positioning: Place the patient lying on the side opposite that being anesthetized. Alternatively, place the patient supine with their leg internally rotated.

Landmarks: Identify the head and neck of the fibula and the common peroneal nerve by palpation.

Needle insertion and direction: Place a skin wheal of local anesthetic solution over the neck of the fibula (**Figure 156-36B**). Insert a 25 gauge needle through the skin wheal to elicit paresthesias. Withdraw the needle 2 mm and allow the paresthesias to resolve. Inject 3 to 5 mL of local anesthetic solution. If paresthesias are not elicited, subcutaneously infiltrate the area with 5 to 7 mL of local anesthetic solution.

US-guided block: The nerve can be blocked with the aid of US. Place the patient prone with a pillow or blanket under their ankle to position the knee in slight flexion (10° to 20°). Identify the biceps femoris muscle laterally, the semimembranosus and semitendinosus muscles medially, and the popliteal crease. Place the US transducer 10 cm proximal to the crease. The sciatic nerve is located between the biceps femoris muscle laterally and the semimembranosus and semitendinosus muscles medially (**Figure 156-35C**). Scan cephalad and caudad to obtain the best view of the sciatic nerve and to identify where the sciatic nerve branches into the tibial and the common peroneal nerves. Move the transducer caudally until the sciatic nerve branches into the tibial nerve medially and the common peroneal nerve laterally.

Place a skin wheal of local anesthetic solution. Place the needle lateral to the long axis of the US transducer. Insert the needle in the plane of the long axis of the US beam. Advance the needle toward the common peroneal nerve. Stop advancing the needle when its tip is adjacent to the common peroneal nerve. Aspirate to ensure that the needle tip is not in a blood vessel. Inject a test dose of 1 to 2 mL of local anesthetic solution. Watch the spread of local anesthetic solution around the common peroneal nerve. If satisfactory, inject 10 to 15 mL of local anesthetic solution to produce the “donut sign.” If the test dose is not satisfactory, reposition the needle and inject another test dose.

Remarks: The common peroneal nerve may not always be palpable. Apply digital pressure over the neck of the fibula. Significant

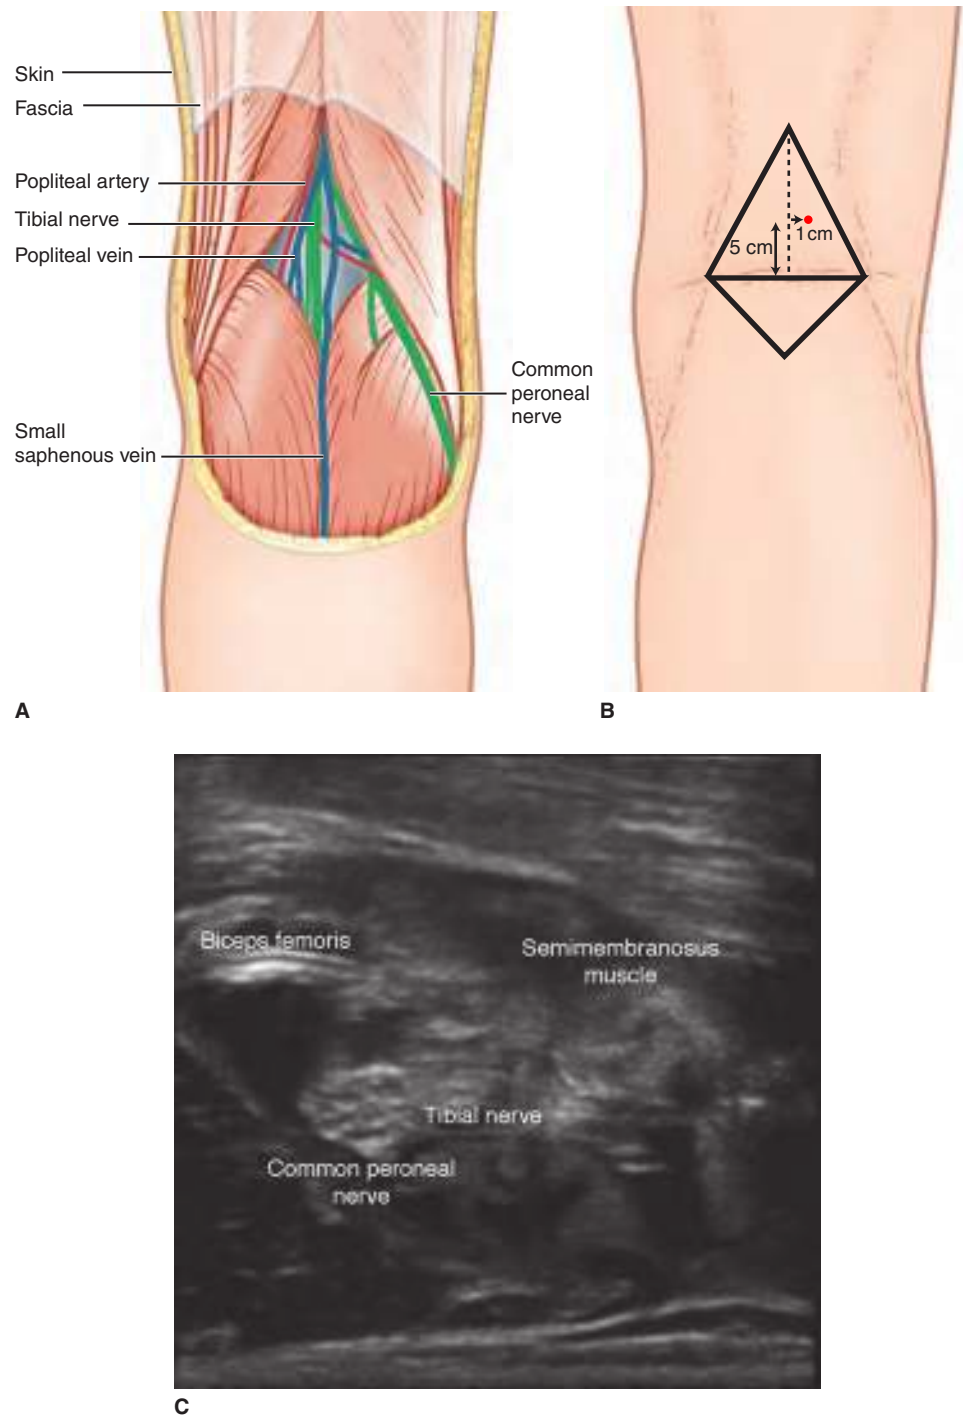

FIGURE 156-35. The anatomic or posterior approach to the popliteal fossa nerve block. **A.** The contents of the popliteal fossa. **B.** Identification of the landmarks required to perform the block. **C.** US image of the popliteal fossa.

discomfort will be elicited when compressing the nerve against the fibula. This site is the location of the common peroneal nerve.

SUPERFICIAL PERONEAL NERVE BLOCK

Anatomy: The superficial peroneal nerve is one of the terminal branches of the common peroneal nerve (Figure 156-37A). It perforates the investing fascia of the anterior leg to become subcutaneous in the lower third of the leg. It provides motor innervation to the peroneus longus and brevis muscles. It provides sensory innervation to the anterolateral leg, medial great toe, and dorsum of the

foot and toes except the first web space and the area covered by the saphenous and sural nerves (Figure 156-27).

Patient positioning: Place the patient supine with their ankle supported on a pillow or blanket.

Landmarks: Identify the anterior border of the medial and lateral malleolus by palpation.

Needle insertion and direction: Place a skin wheal of local anesthetic solution anterior to the distal aspect of the lateral malleolus. Insert a 25 gauge needle through the skin wheal. Infiltrate 6 to 10 mL of local anesthetic solution subcutaneously in a transverse line to the anterior border of the medial malleolus (Figure 156-37B).

FIGURE 156-36. The common peroneal nerve block. **A.** The course of the common peroneal nerve. **B.** The landmark for performing the block.

US-guided block: The nerve can be blocked with the aid of US. Place the US transducer along the anterior border of the lateral malleolus. Identify the dorsalis pedis artery. Use color Doppler to confirm the location of the dorsalis pedis artery. Place a skin wheal of local anesthetic solution. Place the needle lateral to the long axis of the US transducer. Insert the needle in the plane of the long axis of the US beam. Visualize the entire length of the needle as it is advanced in the subcutaneous tissues in a transverse line from the lateral malleolus to the medial malleolus, avoiding the dorsalis pedis artery. Aspirate to ensure the needle tip is not in a blood vessel. Inject 3 to 5 mL of local anesthetic solution as the needle is withdrawn from the medial malleolus to the lateral malleolus.

Remarks: The superficial peroneal nerve may also be blocked at the level of the ankle. Infiltrate 4 to 8 mL of local anesthetic solution subcutaneously in a transverse line from the anterior border of the lateral malleolus to the anterior tibial ridge.

DEEP PERONEAL NERVE BLOCK

Anatomy: The deep peroneal nerve is one of the terminal branches of the common peroneal nerve. It descends over the interosseous membrane into the dorsal foot, lateral to the dorsalis pedis artery (**Figure 156-38A**). It travels between the tendons of the tibialis anterior and extensor hallucis longus muscles at the level of the ankle joint and above. It travels between the tendons of the extensor digitorum longus and the extensor hallucis longus muscles at the level of the malleoli. It may or may not contribute a motor branch to the peroneus longus muscles. It provides sensory innervation to only the first web space (**Figure 156-27**).

Patient positioning: Place the patient supine with their ankle supported on a pillow or blanket.

FIGURE 156-37. The superficial peroneal nerve block. **A.** The course of the nerve. **B.** Blockade of the superficial peroneal nerve.

FIGURE 156-38. The deep peroneal nerve block. **A.** The course of the deep peroneal nerve. **B.** Blockade of the deep peroneal nerve.

Landmarks: Identify the tendons of the tibialis anterior and the extensor hallucis longus muscles by palpation. Identify the anterior tibial artery by its pulse at the level of the ankle joint.

Needle insertion and direction: Place a skin wheal of local anesthetic solution between the two tendons and just lateral to the anterior tibial artery (**Figure 156-38B**). Insert a 25 gauge needle through the skin wheal and perpendicular to the skin. Advance the needle 3 mm and inject 3 to 5 mL of local anesthetic solution.

US-guided block: The nerve can be blocked with the aid of US. Place the US transducer along the line drawn between the anterior border of the lateral and medial malleolus. Identify the tendons of the extensor digitorum longus and extensor hallucis longus muscles and the dorsalis pedis artery. Use color Doppler to confirm the location of the dorsalis pedis artery. Place a skin wheal of local anesthetic solution lateral to the dorsalis pedis artery. Place the needle lateral to the long axis of the US transducer. Insert the needle in the plane of the long axis of the US beam. Visualize the entire length of the needle as it reaches the lateral aspect of the dorsalis pedis artery. Avoid penetrating the dorsalis pedis artery and any tendons. Aspirate to ensure the needle tip is not in a blood vessel. Inject 3 to 5 mL of local anesthetic solution on the lateral aspect of the dorsalis pedis artery. Watch the local anesthetic solution spread around the dorsalis pedis artery.

Remarks: The deep peroneal nerve may also be blocked at the level of the malleoli. Identify the tendons of the extensor digitorum longus and extensor hallucis longus muscles by palpation and the dorsalis pedis artery by its pulse at the level of the malleoli. Place a skin wheal of local anesthetic solution between the tendons and lateral to the dorsalis pedis artery. Insert the needle perpendicular

to the skin. Advance the needle 3 mm and inject 2 to 4 mL of local anesthetic solution.

SURAL NERVE BLOCK

Anatomy: The sural nerve originates from the tibial nerve and the common peroneal nerve in the popliteal fossa. It is superficial after its origin and travels on the lateral leg and foot (**Figure 156-39**). It has already divided at the level of the ankle into numerous superficial branches, all located behind the lateral malleolus. The sural nerve provides sensory innervation to the anterolateral surface of the foot and little toe (**Figure 156-27**).

Patient positioning: Place the patient prone with their ankle supported on a pillow or blanket and the leg externally rotated. Alternatively, place the patient supine with their ankle supported on a pillow or blanket and the leg internally rotated.

Landmarks: Identify the posterior border of the lateral malleolus and the Achilles tendon by palpation.

Needle insertion and direction: Place a skin wheal of local anesthetic solution at the level of the lateral malleolus just lateral to the Achilles tendon. Insert a 25 gauge needle through the skin wheal and angled toward the lateral malleolus (**Figure 156-39**). Infiltrate 5 mL of local anesthetic solution subcutaneously in a transverse line to the lateral malleolus.

US-guided block: The nerve can be blocked with the aid of US. Place the US transducer behind the lateral malleolus. Identify the lateral malleolus. Place a skin wheal of local anesthetic solution. Place the needle lateral to the long axis of the US transducer. Insert the needle in the plane of the long axis of the US beam. Visualize the

FIGURE 156-39. The sural nerve block. **A.** The course of the sural nerve. **B.** Blockade of the sural nerve.

entire length of the needle as it is inserted and contacts the posterior aspect of the lateral malleolus. Aspirate to ensure the needle tip is not in a blood vessel. Inject 3 to 5 mL of local anesthetic solution posterior to the lateral malleolus.

Remarks: Ensure that the needle is not within the Achilles tendon before injecting the local anesthetic solution.

POSTERIOR TIBIAL NERVE BLOCK

Anatomy: The posterior tibial nerve travels in the posterior leg and exists medial to the Achilles tendon several centimeters above the ankle. It is superficial at the ankle, midway between the medial malleolus and the heel (**Figure 156-40**). It lies between the tendons of the flexor digitorum longus and flexor hallucis longus muscles. It travels with and slightly posterior to the posterior tibial artery. The posterior tibial nerve divides at the inferior border of the calcaneus to form the medial and lateral plantar nerves. It provides motor innervation to the intrinsic foot muscles. The lateral plantar nerve provides sensory innervation to the lateral one-third of the sole and plantar surface of the lateral one and one-half toes (**Figure 156-27**). The medial plantar nerve provides sensory innervation to the medial two-thirds of the sole and the plantar surface of the medial three and one-half toes (**Figure 156-27**).

Patient positioning: Place the patient supine with their ankle supported on a pillow or blanket and the leg externally rotated.

Landmarks: Identify the medial malleolus by palpation and the posterior tibial artery by its pulsation.

Needle insertion and direction: Place a skin wheal of local anesthetic solution, at the level of the upper border of the medial

malleolus just posterior to the posterior tibial artery or medial to the Achilles tendon. Insert a 25 gauge needle through the skin wheal and perpendicular to the skin. Advance the needle to the tibia or until paresthesias are elicited. If paresthesias are elicited, withdraw the needle 2 mm and allow them to resolve. Inject 3 to 5 mL of local anesthetic solution. If paresthesias are not elicited, infiltrate 5 to 7 mL of local anesthetic solution starting against the posterior tibia as the needle is withdrawn.

US-guided block: The nerve can be blocked with the aid of US.^{58,59} Place the US transducer behind the medial malleolus (**Figure 156-40B**). Use color Doppler to confirm the location of the posterior tibial artery. Identify the tendon of the flexor hallucis longus lateral to the tibial nerve (**Figure 156-40C**). Place a skin wheal of local anesthetic solution. Place the needle lateral to the long axis of the US transducer (**Figure 156-40B**). Insert the needle in the plane of the long axis of the US beam. Visualize the entire length of the needle as its tip reaches the tibial nerve. Aspirate to ensure the needle tip is not in a blood vessel. Inject 3 to 5 mL of local anesthetic solution around the tibial nerve to produce the “donut sign.”

Remarks: This block is especially useful before exploring puncture wounds, repairing lacerations, or removing foreign bodies from the sole.

ANKLE BLOCK

The ankle block is performed to achieve complete anesthesia of the foot. It requires anesthesia of the posterior tibial nerve, the sural nerve, the superficial peroneal nerve, the deep peroneal nerve, and the saphenous nerve (**Figure 156-41A**). The ankle can be thought of as diamond-shaped in cross-section (**Figure 156-41B**). This diamond requires three subcutaneous and two deep injections (**Figure 156-41B**). The subcutaneous injections are to anesthetize the sural, superficial peroneal, and saphenous nerves. The deep injections are to anesthetize the posterior tibial and deep peroneal nerves. The techniques for these individual nerve block injections were described previously.

DIGITAL BLOCK OF THE TOE

Anatomy: Two dorsal and two volar nerves supply each toe.⁶⁰ These nerves branch from the major nerves of the ankle. The dorsal digital nerves are the terminal branches of the deep and superficial peroneal nerves. The volar nerves are branches of the posterior tibial and sural nerves. The nerves lie in the 2, 4, 8, and 10 o'clock positions.

Patient positioning: Place the patient supine with their hip and knee flexed so that the sole of the foot is flat against the examination table or gurney.

Landmarks: Locate the dorsal aspect of the base of the toe to be anesthetized.

Needle insertion and direction: Place a skin wheal of local anesthetic along the dorsolateral or dorsomedial aspect of the toe. Insert a 25 gauge needle through the skin wheal. Perform the three-sided ring block (**Figure 156-42A**). Direct the needle across the dorsum of the toe and infiltrate 1.0 to 1.5 mL of local anesthetic solution (**Figure 156-42A-1**). Withdraw the needle and reinsert it on the medial aspect of the toe while infiltrating with 1.0 to 1.5 mL of local anesthetic solution (**Figure 156-42A-2**). Repeat the infiltration on the lateral aspect of the toe (**Figure 156-42A-3**). Anesthesia should be complete within 10 minutes. The great toe, due to its unique nerve supply, requires an additional anesthetic injection on the plantar aspect (**Figure 156-42B**).

Remarks: This technique is commonly employed in the Emergency Department. The indications include repair of lacerations,

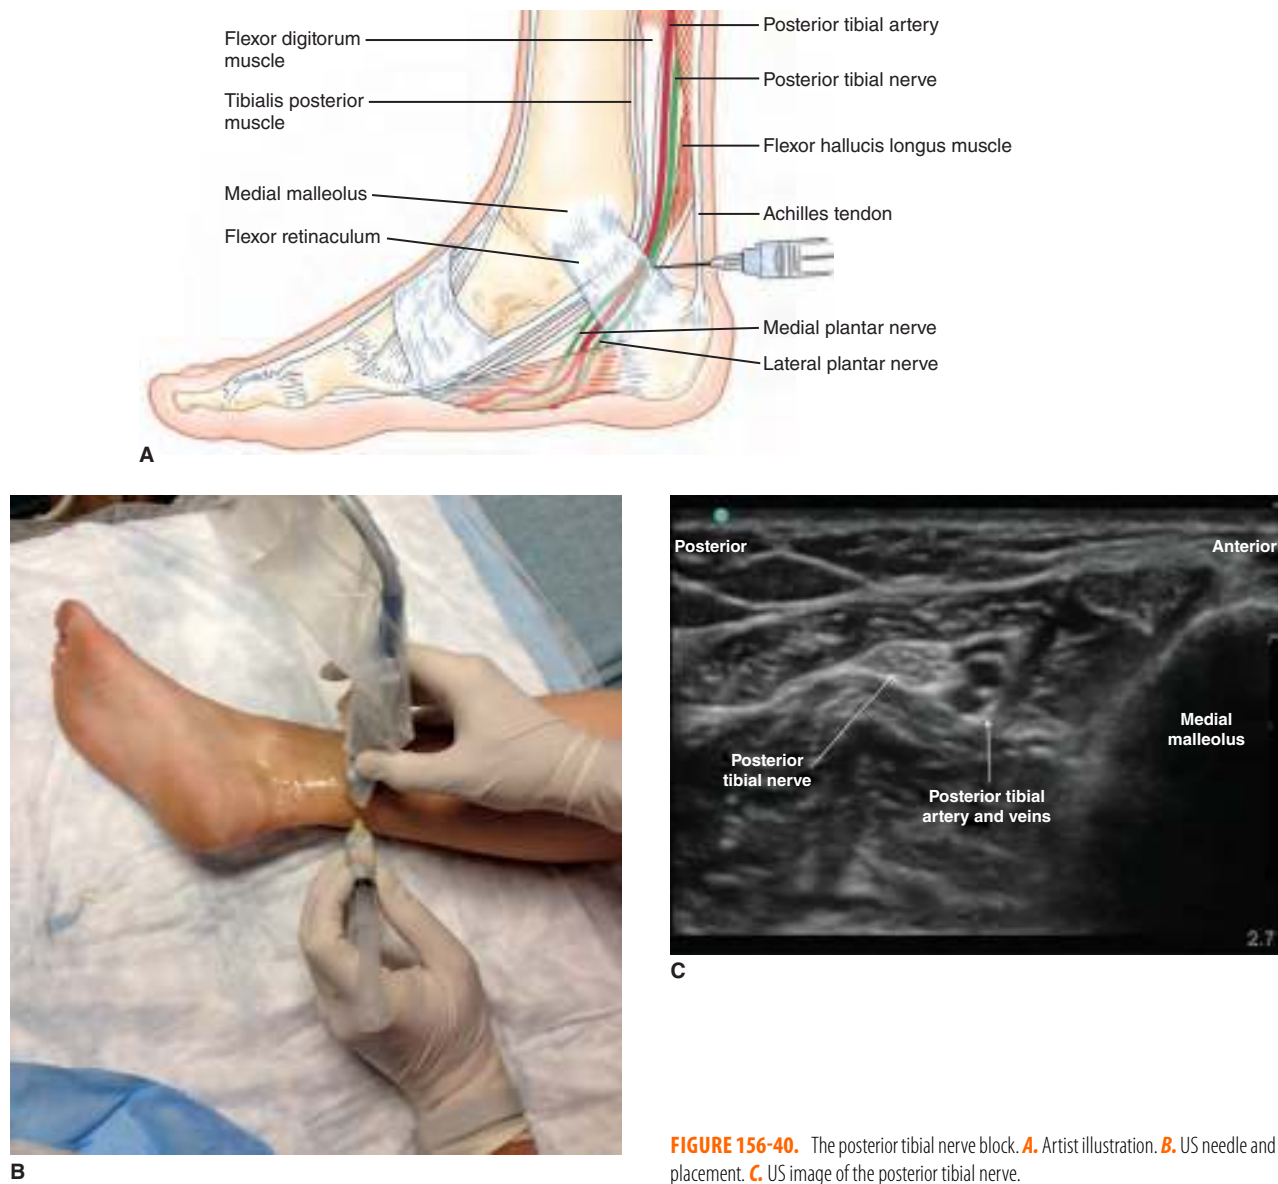

FIGURE 156-40. The posterior tibial nerve block. **A.** Artist illustration. **B.** US needle and transducer placement. **C.** US image of the posterior tibial nerve.

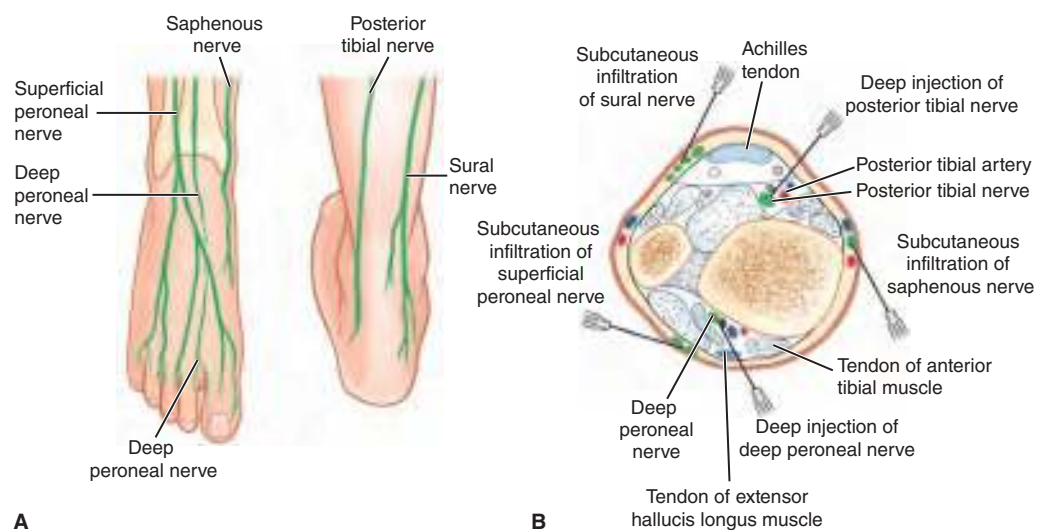

FIGURE 156-41. The ankle block. **A.** The five nerves that provide sensory innervation to the foot. **B.** Blockade of the five nerves.

FIGURE 156-42. The digital block of the toe. **A.** The three-sided ring block may be used on any of the toes. **B.** The great toe requires an additional injection to achieve anesthesia.

incision and drainage of infections, removal of toenails, manipulations of fractures and dislocations, and painful procedures requiring anesthesia. Other techniques to anesthetize the toes are similar to those of anesthetizing the fingers (Figure 156-24).

ASSESSMENT

Allow 5 to 10 minutes for most regional anesthesia blocks to take effect. Up to 20 minutes may be required for blockade of major nerves (i.e., axillary, femoral, sciatic, and popliteal fossa). **Incomplete or inadequate anesthesia is the result of not properly identifying the anatomic landmarks or not inserting the needle properly. The procedure may be repeated if the administration of a second dose of local anesthetic solution does not result in the patient receiving a toxic dose of the anesthetic agent (Table 156-2).**

AFTERCARE

Perform frequent neurovascular checks until baseline function has returned. Injury to the anesthetized limb can result if the patient is permitted to use it, to use heat or cold application, or to perform wound care before the anesthesia has worn off.²¹ If extensive or major nerve blockade was performed, discharge the patient home only after the sensation and function have returned to baseline. The patient may be discharged home immediately after minor blockade but should be properly cautioned. Avoid compression dressings as they may result in ischemia which is improperly sensed by the anesthetized area or limb.

COMPLICATIONS

Complications can occur from the injection of local anesthetic solution, most of which are minor. Significant complications are rare; yet, they do occur. Complications generally result from poor technique. General precautions include measures to minimize nerve injury, intravascular injection, and systemic toxicity. The Emergency Physician must be prepared to institute quick and immediate abortive care, cardiac monitoring, and airway control if complications do arise.

ALLERGIC REACTIONS

Allergic reactions can occur from hypersensitivity to the local anesthetic solution. Symptoms can range from mild itching and urticaria to circulatory collapse and death. Severe allergic reactions are

extremely rare but may occur. The preservative in the local anesthetic solution is often the cause of an allergic reaction. Local anesthetic solutions containing no preservatives are an alternative. One example is “cardiac” lidocaine that is used for Advanced Cardiac Life Support (ACLS) protocols. Topical ice or vapor coolant is an acceptable alternative to nothing if one is concerned about a potential allergic reaction from the local anesthetic solutions. A solution of 1% to 2% diphenhydramine can also be used as an injectable local anesthetic.⁸ Refer to Chapters 153 and 154 for the complete details of alternative anesthetic techniques.

HEMORRHAGE

Significant bleeding is extremely rare. Injection of a local anesthetic solution can be performed safely in patients who are anticoagulated or have a bleeding disorder.⁸ A hematoma may commonly develop due to an arterial puncture. The application of direct pressure can be helpful if significant external hemorrhage occurs. However, if bleeding continues, treatment may be required to reverse the anticoagulant or replace clotting factors.

OVERDOSAGE

Central nervous system (CNS) complications primarily result from local anesthetic toxicity. These symptoms range from tremors to convulsions. The most severe complication is respiratory compromise resulting in intubation. The maximum dose of local anesthetic solution should not exceed the doses listed in Table 156-2.^{8,10} Toxicity after intravascular injection requires even less anesthetic than subcutaneous infiltration. Refer to Chapter 153 for the details of local anesthetic toxicity and its management.

INFECTION

Infection can occur when the needle penetrates unclean skin. The risk of infection is significantly reduced if proper aseptic technique is used. The risk of infection is negligible when the skin is properly cleansed, sterile technique is used, puncture through obviously infected skin is avoided, and penetrating the needle through a skin lesion that may harbor microorganisms is avoided.

VASOVAGAL REACTIONS

The patient may experience an increase in vagal tone from apprehension, needle phobias, and/or pain. Vasovagal reactions are relatively common and may be associated with light-headedness and/or fainting. **Always perform regional anesthesia with the patient on a stretcher or in a chair that reclines to prevent secondary injury.** Vasovagal reactions are self-limited and only require reassurance.⁸

NERVE INJURY

Inflammation of the nerve is the most common nerve injury seen after regional anesthesia. Neuritis is a rare complication. Patients may complain of paresthesias, motor deficits, and/or sensory deficits. Most cases are transient and resolve completely, requiring only supportive care and close follow-up. Nerve damage results from direct needle trauma, ischemia due to intraneural injection, and chemical irritation from the anesthetic solution.^{60,61} Proper needle style, positioning, and manipulation can minimize direct nerve damage. Intraneural injection can cause nerve ischemia with resultant injury. **Elicitation of paresthesias or severe pain indicates that**

the needle has made contact with the nerve. Withdraw the needle slightly and allow the paresthesias to resolve before injecting the local anesthetic solution. Concentrated anesthetics can produce chemical irritation of the nerve.

COMPARTMENT SYNDROME

A compartment syndrome is more frequently associated with the injury, not the regional nerve block, in most cases.^{62,63} A concern is that the regional nerve block will affect the patient recognizing the changes of a developing compartment syndrome. Refer to Chapters 93 and 94 for a more detailed discussion of a compartment syndrome.

INTRAVASCULAR INJECTION

Intravascular injection results in both systemic and limb toxicity. Inadvertent intravascular injection produces high blood levels of the anesthetic agent and resultant toxicity. Particular care must be taken when administering large amounts of local anesthetic solution in close proximity to large blood vessels.

Intraarterial injection of local anesthetic solution containing epinephrine may cause peripheral vasospasm and subsequent ischemia that further compromises injured tissue. The local anesthetic solution is not toxic to the limb itself, although it may produce transient blanching of the skin by displacing blood from the vascular tree. Alpha-adrenergic antagonists have been used with success in relieving arterial vasospasm secondary to intraarterial injection of local anesthetics.⁶⁴

ULTRASOUND-ASSOCIATED COMPLICATIONS

The use of US during the establishment of regional nerve blocks is associated with several complications and pitfalls. The chance of a nerve injury, intraneural injection, or intravascular injection is higher if a regular (i.e., cutting) needle is used. Always use a non-cutting needle for nerve blocks. Ensure the identification of blood vessels by routinely turning on the power Doppler window when scanning for nerves. Accidental intravascular injection of large quantities of local anesthetic agents can lead to seizures, arrhythmias, apnea, and death. Failure to “pop” through the nerve sheath will not produce the “donut sign” and will likely lead to a failed block.

There is no standardized training for the Emergency Physician to learn how to perform US-guided nerve blocks. Regional anesthesia has evolved into an Anesthesia subspecialty and brachial plexus blocks can take considerable time to master. The use of phantom and simulation models for training, as well as careful supervision, are highly recommended. Novice sonographers may want to start with forearm, femoral nerve, popliteal, and leg blocks before tackling brachial plexus blocks.

SUMMARY

Regional anesthesia can serve as a valuable adjunct to the Emergency Physician's armamentarium. It is used for wound anesthesia prior to exploration, irrigation, debridement, and repair. Regional anesthesia may also be used to reduce the pain of procedures such as reduction of fractures and dislocations. Nerve blocks are especially useful when pain-sensitive structures such as fingers, toes, hands, and feet are involved. The application of regional anesthesia is frequently overlooked and underutilized in the emergency care

of not only adults but even more so in the case of children. The use of regional nerve blocks is simple, safe, and effective for providing analgesia in the Emergency Department.

Intravenous Regional Anesthesia

Christopher Freeman and Emily Cooper

INTRODUCTION

The technique of intravenous regional anesthesia (IVRA) was first introduced by August Bier in 1908.¹ IVRA essentially consists of injecting local anesthetic solution into the venous system of an extremity that has been exsanguinated by compression and/or gravity and isolated from the central circulation by means of a tourniquet. Procaine in concentrations of 0.25% to 0.5% was injected through an intravenous cannula placed between two Esmarch bandages used as tourniquets to divide the arm into proximal and distal compartments in Bier's original technique.²⁻⁴ He noted two distinct types of anesthesia. The first was an almost immediate onset of "direct" anesthesia between the two tourniquets. An "indirect" anesthesia distal to the distally placed tourniquet was noted after a delay of 5 to 7 minutes. This technique was eventually renamed the Bier block.

Bier performed dissections of the venous system of the upper extremity in cadavers after injecting methylene blue. He was able to determine that the "direct" anesthesia was the result of the local anesthetic agent bathing bare nerve endings in the tissues. The "indirect" anesthesia was most probably due to the local anesthetic agent being transported into the substance of the nerves via the vasa nervorum where a conduction block is affected. Bier's conclusion was that there were two mechanisms of anesthesia associated with his technique: a peripheral infiltration block and a conduction block.

The only major modification of Bier's technique in the past 100 years has been the development of the double tourniquet technique in current clinical practice.⁵⁻⁷ The Bier block is appropriate for brief surgical procedures of the upper or lower extremity. The technique has certainly gained its greatest acceptance for use in the upper extremity as tourniquet problems and safety issues seem to arise more frequently when IVRA is undertaken in the lower extremity.

The Bier block is a procedure that has found utility as a treatment adjunct for patients suffering from complex regional pain syndromes (CRPS; formerly known as reflex sympathetic dystrophy [RSD] or sympathetically maintained pain) as an alternative to repeated sympathetic blocks. Chemical sympathectomy using IVRA with agents such as guanethidine or bretylium may last up to 5 days as compared to local anesthetic blocks that typically provide analgesia lasting only hours.

ANATOMY AND PATHOPHYSIOLOGY

Lidocaine is the most commonly used local anesthetic agent for IVRA in the United States. Prilocaine is more routinely chosen in Europe. Prilocaine is metabolized to orthotoluidine, an oxidizing compound capable of converting hemoglobin to methemoglobin. This is usually only of concern when the dose of prilocaine is greater than 600 mg. Lower extremity IVRA using volumes up to 100 mL does not approach this dosage.

The usual dose of lidocaine to administer is approximately 3 mg/kg. This is a relatively large dose in terms of potential systemic toxicity. Systemic toxic reactions can and do occur due to leakage past the tourniquet, sudden accidental deflation of the tourniquet during the procedure, or intentional deflation following brief surgical procedures.^{8,9}

An alternative dose of 1.5 mg/kg of lidocaine to a maximum of 100 mg has been shown to be effective in 95% of patients for reduction of closed fractures.¹⁰ Another study demonstrated that a single forearm tourniquet and 150 mg of lidocaine in adults provided superior analgesia compared with the standard upper arm tourniquet and 300 mg lidocaine dose.¹¹ The advantage of this decreased dose of lidocaine is the greater therapeutic window and decreased chance of toxicity from accidental or early tourniquet release.

There are multiple studies looking at adjuvant medicine added to local anesthetic agents.^{12–36} These adjuvants have the theoretical benefit of improved pain control both during and after the procedure as well as decreased risk of systemic toxicity from the local anesthetic agents as a result of the decreased required dose. Agents studied include acetaminophen, benzodiazepines, bicarbonate, clonidine, dexmedetomidine, dexamethasone, ketorolac, and opiates among others.

Opiate receptors exist in the peripheral nervous system.^{12,13} It has been demonstrated that opioids may produce effective, long-lasting analgesia when injected with local anesthetics for brachial plexus blockade.^{14–18} Several investigators have attempted to decrease the potential for lidocaine toxicity by adding opioids to reduce the volume of lidocaine. The addition of fentanyl to lidocaine for IVRA results in improved analgesia while reducing the risks of lidocaine toxicity.^{19,20} Other investigators have found that adding an opioid and a muscle relaxant to 0.25% lidocaine provides the same analgesia and muscular relaxation as 0.5% lidocaine alone and reduces the likelihood of systemic toxicity.

Adjuvants added to 0.25% lidocaine have included fentanyl plus pancuronium, fentanyl plus rocuronium, and fentanyl plus D-tubocurarine.^{21–24} The authors reported outstanding operating conditions in each of these cases. The lidocaine concentration was reduced in half and the potential for systemic toxicity was halved. A small dose of any nondepolarizing muscle relaxant may be chosen as an adjunct to the local anesthetic. **Avoid using D-tubocurarine as it releases histamine.**

Other agents used in an attempt to improve IVRA have included bicarbonate, butorphanol, clonidine, dexmedetomidine, dexamethasone, ketorolac, and ondansetron.^{25–30} Adding ketorolac to the IVRA leads to less tourniquet pain and improved postoperative analgesia.^{25–27} Clonidine and dexmedetomidine, both α -2-adrenoceptor agonists, have shown some benefit in decreasing tourniquet pain and in improving postoperative analgesia.^{31,32} Both have the possible side effects of sedation and hypotension upon cuff deflation which may

limit their clinical use. In limited studies, dexamethasone 8 mg intravenously has shown some efficacy in improved postoperative analgesia.^{27,33} Alkalinization of the local anesthetic with bicarbonate may improve pain upon injection.^{34,35} This has not been demonstrated to hasten the onset or prolong the duration of anesthesia. Midazolam (40 to 50 μ g/kg) has shown some benefit in decreasing intraoperative as well as postoperative pain.³⁶ Of all the agents described above, ketorolac 20 to 60 mg intravenously seems to have the largest clinical benefit with the least side effects.

Prilocaine is usually selected for IVRA in countries outside the United States. The addition of opioids to prilocaine has not been shown to improve success with the technique.^{37–39} The addition of bicarbonate to prilocaine shortens the onset time of anesthesia and prolongs the duration of anesthesia.^{40,41} The addition of clonidine to prilocaine dramatically suppresses tourniquet pain but does not alter postoperative pain following tourniquet deflation.⁴²

The addition of long-acting and potent lipophilic opioids with agonist-antagonist activity (e.g., buprenorphine) to local anesthetics administered for brachial plexus blockade has been demonstrated to provide effective anesthesia and long-lasting postblock analgesia. This technique is a single-shot procedure and may supplant other methods of anesthetizing the upper extremity and perhaps the lower extremity. It offers a method of prolonging pain management long into the recovery period which IVRA does not.¹⁸

INDICATIONS

IVRA is appropriate for procedures, surgeries, and manipulation of the extremities requiring anesthesia of up to 1 hour in duration. The advantages are numerous (**Table 157-1**). It is most suited for laceration repair, reduction of fractures and dislocations, burn care, and minor soft tissue procedures in the Emergency Department.^{43–47} The necessity of exsanguinating the extremity is a potentially painful maneuver that may preclude certain procedures from being undertaken with this technique. The Bier block is acceptable in the anticoagulated patient, a feature that distinguishes this technique from other regional anesthesia procedures (e.g., spinal block, epidural block, or plexus blocks).

CONTRAINDICATIONS

The only absolute contraindications for IVRA is patient refusal and allergy to local anesthetic agents. Relative contraindications include crush injuries of an extremity, the inability to obtain peripheral

TABLE 157-1 Advantages of IVRA

Always gets muscular relaxation
Can be used in patients over the age of 2 years (14 kg)
Does not require specific anatomic knowledge
Duration of action is related to on-time of tourniquet
Easy technique
Effective in 96% to 100% of cases
Low cost compared to other sedation techniques
Low toxicity
Minimal adverse effects
Minimal complications
Minimal supplementary drugs required
Neurologic examination possible after procedure
No restrictions on preoperative states
Quick offset
Quick onset
Short Emergency Department stay
Short recovery time allows examination
Well accepted by patients

venous access in the affected extremity, uncontrolled hypertension, local skin infections, cellulitis, and compound fractures. Do not perform IVRA in a patient with prior intravascular thrombosis or with conditions that predispose them to intravascular thrombosis (e.g., malignancies, Raynaud's disease, protein C or S deficiency). Patients with severe vascular injuries to the extremity requiring treatment are not suitable candidates for IVRA. Exclude patients with arteriovenous fistulas from consideration as well as anyone else in whom a tourniquet is unsuitable (e.g., severe peripheral vascular disease or progressive peripheral nerve disorders). The feasibility of using a pneumatic tourniquet in a patient with sickle cell disease must be balanced against the need for performing this type of anesthesia. Tourniquet use in sick patients may induce localized stasis of blood flow, acidosis, and hypoxemia with subsequent formation of sickle cells and a pain crisis. Liver disorders are relative contraindications. The local anesthetic is metabolized by the liver and can cause toxicity if it is metabolized slower.

Never perform IVRA using blood pressure cuffs if a pneumatic tourniquet is not available. Blood pressure cuffs are not designed to stay inflated for prolonged periods of time at high pressures. They can spontaneously deflate from a small leak and result in local anesthetic entering the central circulation and causing toxicity.

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- Alcohol swabs
- Gauze 4×4 squares
- Local anesthetic solution, 0.25% to 0.50% lidocaine hydrochloride or 0.50% prilocaine
- Penrose drain, 12 to 18 inches long and 7/8 inches wide
- 18 to 20 gauge angiocatheter
- 500 to 1000 mL bag of intravenous solution connected to an infusion set
- Intravenous catheter
- Crystalloid solution
- Intravenous infusion set
- Two single or one dual pneumatic tourniquet, size appropriate for the extremity
- Cotton cast padding
- Esmarch bandages, 60 inches long and 4 inches wide
- 50 mL Luer-lock syringe
- 100 mL sterile graduated measuring cup for mixing of solutions
- Adhesive tape
- Cardiac monitor
- Noninvasive blood pressure cuff
- Pulse oximeter
- Resuscitation equipment
- Adjuvants to local anesthesia (e.g., parenteral analgesics and sedatives)

PATIENT PREPARATION

Explain the procedure, its risks, and benefits to the patient and/or their representative. Discuss the discomfort that may be experienced during the procedure. Obtain an informed consent to perform the procedure in addition to a consent for the procedure to be performed under the influence of the Bier block. Place the patient supine on a gurney. Alternatively, place the patient in any other position so long as the vein selected for placement is readily

accessible. Assemble all of the required equipment (**Figure 157-1**). Test the pneumatic tourniquets to ensure they remain inflated and do not have a leak.

Obtain intravenous access in the affected extremity with a saline-locked angiocatheter. The addition of intravenous extension tubing to the angiocatheter is optional and preferred by some Emergency Physicians. Place the angiocatheter in the dorsum of the hand for procedures involving the upper extremity. Place the angiocatheter in a foot, ankle, or lower leg vein for lower extremity procedures. Obtain a second intravenous access in a nonprocedural extremity. Alternatively, central venous access may be secured if required for other reasons.

Place the patient on the cardiac monitor, noninvasive blood pressure cuff, and pulse oximeter. Obtain, record, and assess baseline vital signs. Administer small aliquots of intravenous analgesics (i.e., 1 to 2 µg/kg fentanyl) if the patient is in severe pain to facilitate the exsanguination procedure. **Total patient cooperation is not essential to be successful. This method of anesthesia is not indicated if the patient is persistently combative and unable to follow commands.** Administer small doses of benzodiazepines (e.g., 15 to 25 µg/kg midazolam) for anxiolysis if needed. An important added benefit to choosing a benzodiazepine is the suppression of the usual convulsant response associated with local anesthetic toxicity, a valid concern in the patient receiving IVRA. **Check to ensure that resuscitative equipment is present and working properly. The time to look for resuscitative equipment is not when it is needed.**

UPPER EXTREMITY TECHNIQUE

APPLICATION OF THE PNEUMATIC TOURNIQUET

Apply two single tourniquets or a double pneumatic tourniquet over cotton cast padding (**Figure 157-2**). Place one single cuff or the double cuff high on the upper arm. Place the second single cuff above the angiocatheter and just below the proximal cuff. Elevate the arm for 1 minute. Tightly apply a rubber Esmarch bandage spirally around the arm starting at the hand and terminating at the distal cuff of the double tourniquet (**Figure 157-3**). The process of arm elevation followed by the application of an Esmarch bandage exsanguinates the arm. Place the tourniquets about the elbow and proximal forearm for procedures of the hand, wrist, and distal forearm (**Figure 157-4**).

Apply digital pressure to occlude the axillary artery. Inflate the proximal cuff of the tourniquet to between 50 and 100 mmHg above the patient's systolic blood pressure. **Wrap tape around the tourniquet to ensure there is not failure of the Velcro or manual ties and the cuff spontaneously opens allowing the local anesthetic solution to access the central circulation. It is important to compress the axillary artery both before and during the inflation of the pneumatic tourniquet.** Venous outflow is prevented before arterial inflow is occluded as the pressure in the tourniquet rises. Exsanguination of the extremity may be incomplete without occlusion of the arterial inflow before the tourniquet is inflated. Remove the Esmarch bandage. The arm should remain pale. Palpate the proximal cuff of the tourniquet to ensure it remains inflated.

It is essential to test for arterial occlusion by palpation of the radial artery before the injection of the local anesthetic solution. Confirm the absence of the radial pulse. Do not proceed with the procedure if the radial pulse is still present. Deflate the tourniquet and reattempt the procedure.

INJECTION OF THE LOCAL ANESTHETIC AGENT

Slowly inject 30 to 50 mL, maximum 3 mg/kg, of 0.5% lidocaine hydrochloride through the IV catheter in the arm where the tourniquet was applied. An alternative is to inject 10 to 15 mL of 1%

A

or 2% lidocaine. The precise volume depends upon the size of the arm being anesthetized and the maximal anesthetic dose based on the patient's weight (Table 153-1). **Slow and controlled injection rates are an absolute necessity to avoid the development of elevated venous pressures.** Remove the angiocatheter and apply pressure over the skin puncture site. The onset of anesthesia begins in approximately 5 to 7 minutes. Begin the procedure for which the IVRA was performed once adequate anesthesia is obtained.

If the patient develops tourniquet pain or the procedure duration is longer than 30 minutes, inflate the distal cuff to 100 mmHg above the patient's systolic blood pressure. Palpate the distal cuff of the tourniquet to ensure it remains inflated. **Wrap tape around the distal cuff of the tourniquet to ensure there is not failure of the Velcro or manual ties and it spontaneously opens allowing the local anesthetic solution to access the central circulation.** Remove the tape on the proximal cuff and slowly deflate it. Inflation

FIGURE 157-2. Preparatory steps. An angiocatheter is inserted into a dorsal hand vein. The double tourniquet is applied to the upper arm after the application of protective padding.

of the distal cuff over the anesthetized area and deflation of the proximal cuff will minimize the development of tourniquet pain.

LOWER EXTREMITY TECHNIQUE

The lower extremity requires double the anesthetic volume for IVRA and is otherwise completely analogous to the upper extremity. Obtain intravenous access in the lower extremity. Place the proximal single or double tourniquet just distal to the femoral pulse. Place the distal single tourniquet just above the site of the procedure. Elevate and exsanguinate the extremity. Apply digital pressure to the femoral artery while inflating the proximal tourniquet. Inject the local anesthetic agent. Inflate the distal tourniquet and deflate

FIGURE 157-3. Exsanguination of the arm. The patient's arm is elevated and an Esmarch bandage is tightly applied.

FIGURE 157-4. A modified setup for procedures involving the hand, wrist, and distal forearm.

the proximal tourniquet. Perform the procedure for which IVRA was performed.

A modification of the above technique can be performed for procedures about the distal leg, ankle, and foot (**Figure 157-5**). Place the proximal tourniquet just above the knee joint and the distal tourniquet just below the knee joint. There is one major advantage of this technique. It allows the same volume of local anesthetic agent to be used as would be used for the upper extremity in the same patient. This is half of the volume required for the entire leg.

ALTERNATIVE TECHNIQUES

Some patients, especially those with painful fractures of the upper or lower extremity, may not be able to tolerate the placement of an Esmarch bandage for exsanguination of the extremity. It may

FIGURE 157-5. Placement of the double tourniquet for IVRA of the foot, ankle, and distal leg.

be completely appropriate to forego the Esmarch bandage. Elevate the extremity while occluding the axillary artery for a minimum of 5 minutes to affect the requisite venous drainage of the extremity before inflating the pneumatic tourniquet.

Exsanguination may be painlessly and effectively accomplished using a zippered pneumatic splint if simply elevating the extremity is not sufficient to affect this process and IVRA is still considered the technique of choice.⁴⁸ Apply two single tourniquets or the double tourniquet. Place the patient's extremity on the open splint and close the zipper. Inflate the splint to a pressure well above the patient's systolic blood pressure. Inflate the proximal cuff of the tourniquet. Deflate and remove the splint. The gradual inflation of the pneumatic splint is usually more comfortable whereas applying an Esmarch bandage to a painful fracture produces excessive pain. This improves the likelihood of the patient accepting the technique and enhances the chance for success with IVRA.

An alternative method for procedures involving the hand, wrist, and distal forearm is placing a single cuff on the proximal forearm (**Figure 157-4**). This technique has two main benefits. It allows for a lower dose of lidocaine (1.5 mg/kg to a maximum of 150 mg), which decreases the chance of systemic toxicity, it causes less pain at the tourniquet site, and less need for rescue medications during the procedure.^{11,49} **This is the preferred method for injuries involving the hand, wrist, and distal forearm.** The remainder of the technique is the same as described for the upper extremity.

Studies have achieved success using a single tourniquet distal to the elbow for forearm IVRA. The smaller area allows for decreased lidocaine requirements, which lessens the concern for systemic toxicity after deflation. The smaller doses of lidocaine allow for decreased inflation time of the tourniquet, resulting in less tourniquet-related pain and faster overall procedure time. The risk of using a single tourniquet lies in the lack of a backup in case of tourniquet failure, leading to systemic dissemination of the anesthetic agent. More research must be done before the single tourniquet technique is appropriate for use in the Emergency Department.^{11,49}

DEFLATION OF THE PNEUMATIC TOURNIQUET

Deflation of the tourniquet after the procedure has been performed is a critical step to minimize the possibility of toxicity associated with IVRA. **It is absolutely mandatory that the tourniquet not be deflated unless at least 30 minutes have elapsed since the injection of the local anesthetic agent, even if the duration of surgery or manipulation has been very brief.** At least one case of cardiac arrest has been reported when the tourniquet was released soon after the injection of the local anesthetic solution.⁵⁰

It is absolutely mandatory to deflate the tourniquet in a cyclical fashion. Remove the tape from the cuff. **Deflate the cuff and immediately reinflate it to 50 to 100 mmHg above the patient's systolic blood pressure.** Observe the patient for 1 or 2 minutes and question them carefully for the occurrence of symptoms associated with local anesthetic toxicity (e.g., tinnitus, lightheadedness, or a metallic taste in their mouth). Signs of central nervous system stimulation may represent local anesthetic toxicity. If there are no signs or symptoms after approximately 1 or 2 minutes, deflate the cuff and once again immediately reinflate the cuff. Observe the patient for a period of approximately 1 to 2 minutes and question them again for the symptoms associated with local anesthetic toxicity. Repeat this process a third time. The tourniquet may be safely deflated and removed if there are no signs and symptoms of local anesthetic toxicity after three cycles of deflation and reinflation of the cuff. The safety of the cycled deflation and reinflation allows only a small fraction of the administered and unbound local anesthetic to enter

the systemic circulation each time.⁵¹ This minimizes the possibility of a sudden sustained increase in the blood level of the local anesthetic agent.⁵¹

ASSESSMENT

Patients must be carefully observed for the signs and symptoms of local anesthetic systemic toxicity (LAST) following injection of local anesthetic agents for IVRA. Remain in verbal contact with the patient. Continually monitor the patient's vital signs (i.e., cardiac monitor, blood pressure, pulse, and oxygen saturation). Adjuvants added to the local anesthetic agent may result in concomitant side effects or toxicities unrelated to the local anesthetic. Muscle relaxants can result in patients developing muscle weakness if they gain access directly into the systemic circulation. This may necessitate assisted ventilation, controlled ventilation, or the establishment of an airway if symptoms are severe. Opioids can result in signs of sedation and respiratory depression. This is quite rare following the small doses of opioid that would normally be administered as supplementation for IVRA.

Ensure that IVRA has been effective in providing appropriate analgesia for the intended surgery or manipulation to proceed uneventfully. The success rate with IVRA has been reported to be as high as 96% in one large series of patients.⁵² Supplemental local anesthesia, intravenous sedatives and analgesics, or general anesthesia may be required if IVRA is unsuccessful or only partially effective in preventing nociceptive stimuli (i.e., pain) from being experienced by the patient.

Patients must be treated with standard basic and advanced cardiac and pulmonary life support protocols. Administer oxygen first if toxicity or complications develop following IVRA.

The patient assessment does not end after completing the mechanical portion of IVRA. Tourniquet problems may develop during the procedure and result in leakage of local anesthetic and/or adjuvant into the systemic circulation. **Release and deflation of the tourniquet may be associated with significant morbidity if strict adherence to the guidelines in this text are not followed.**

AFTERCARE

Carefully observe the patient after IVRA has been completed. It is important to keep the extremity relatively quiescent in the immediate postprocedural period. Remove the intravenous cannula and apply a sterile dressing over the injection site. Assess the extremity for signs of venous or arterial insufficiency every 30 minutes or at more frequent intervals if necessary. Peripheral nerve function will rapidly return following the deflation of the tourniquet and should be examined and documented. Continually monitor vital signs at intervals no longer than every 5 minutes for the first 30 minutes and as indicated by the patient's clinical status thereafter. Additional intravenous or intramuscular analgesics may be administered at this time if the patient is experiencing pain as IVRA affords no prolongation of antinociception once the tourniquet has been deflated.

Patients must be able to bear weight and ambulate (if appropriate) prior to being discharged if the lower extremity was chosen for IVRA. Patients may be discharged into the care of a responsible adult or back to their respective units once they meet the established criteria if there have been no untoward effects of the procedure and the IVRA. Instruct the patient regarding the use of the extremity depending, of course, on the nature of the intervention performed upon it.

Perform a detailed follow-up within 24 hours either by telephone for outpatients or in person for inpatients. Place the emphasis on peripheral sensory, motor, and sympathetic nerve function.

COMPLICATIONS

Local anesthetic agents have relatively narrow therapeutic indices. LAST involves primarily the central nervous system and the cardiovascular system. There may be localized neural and skeletal muscle irritation or allergic phenomena, all supporting vigilance following injection for IVRA. LAST usually progresses through several well-defined stages unless a gross overdosage has been directly administered systemically. These include numbness of the tongue and lightheadedness followed by visual and auditory disturbances. This progresses to muscular twitching, unconsciousness, convulsions, coma, respiratory depression, cardiovascular depression, and death in the absence of treatment. Reversal of the effects may be obtained by lipid emulsion infusion. Multiple case reports and animal studies support the use of lipid emulsion in patients with significant overdoses. The standard dose is 1.5 mL/kg of 20% lipid emulsion followed by an infusion of 0.25 to 0.5 mL/kg/min for 20 minutes.⁵³ Further information on lipid emulsion therapy can be found in Chapter 153 and at www.lipidrescue.org/.

These events progress along plasma concentrations of about 3 to 24 µg/mL of lidocaine for the most severe signs and symptoms. A correlation exists between the convulsive blood level of various local anesthetic agents and their relative anesthetic potencies. Prilocaine and lidocaine are on the lower, least potent, and least toxic end of that spectrum. The rate of injection and the rapidity with which a particular blood level is achieved will influence the toxicity of these agents.

The patient's acid-base status will have a profound influence on the central nervous system activity of the local anesthetic agent. Convulsive thresholds are inversely related to arterial PaCO₂. This further emphasizes the importance of continually assessing patients verbally and by noninvasive monitors following the injection of the local anesthetic. Avoid oversedation as it tends to result in respiratory depression and elevation of arterial CO₂.

Lidocaine is well known to depress the maximal rate of cardiac depolarization and cardiac contractility while not significantly altering the resting membrane potential of cardiac muscle. **Continually assess the cardiac monitor during and after the injection of lidocaine for IVRA.** Blood pressure monitoring is mandatory since local anesthetics exert a biphasic action on smooth muscle of peripheral blood vessels. Vasoconstriction is seen early followed by vasodilatation if levels continue to rise. Strict adherence to the recommended doses presented in this chapter will prevent most of the complications due to excessive dosing.

Lidocaine and prilocaine are both amino-amide-type local anesthetic agents having pKa values of 7.7 and are between 55% and 65% protein bound. They react rather similarly when used for IVRA. **Assess the patient for the development of methemoglobinemia if prilocaine is administered for IVRA.** The methemoglobinemia resulting from prilocaine is spontaneously reversible. It can alternatively be corrected by administering intravenous methylene blue. The incidence of allergic reactions associated with the use of lidocaine and prilocaine is not common because amino-amide agents are not derived from para-aminobenzoic acid (PABA). **Patients must be monitored for the development of allergic reactions following injection for IVRA.**

Complications due to IVRA may be classified as drug-related or tourniquet-related.⁵⁴ Drug-related complications depend both on the agent being administered directly into the vascular system and the equipment used to isolate the vascular space from the systemic circulation. Inadvertent deflation of the cuff, cuff failure, a sudden increase in venous pressure within the occluded tissue to a level higher than cuff pressure, and an intact interosseous circulation may all contribute to drug-related complications when using IVRA.

Lidocaine is the most commonly used local anesthetic for IVRA and is therefore the agent about which most complications have been reported. Lidocaine does not accumulate to any great extent at sodium channels at therapeutic plasma concentrations.^{55,56} Toxic accumulation of the drug at the sodium channels is atypical since it rapidly binds to and dissociates from the channel.^{55,56} Excessive plasma concentrations of lidocaine associated with intravenous boluses of large doses with a faulty tourniquet system result in peripheral vasodilatation and diminished cardiac contractility that manifests clinically as hypotension. The onset and termination of lidocaine anesthesia are relatively rapid.⁵⁷ The usual onset of IVRA using 0.5% lidocaine is approximately 4.5 ± 0.3 minutes. The termination of anesthesia once the tourniquet has been totally deflated is approximately 5.8 ± 0.5 minutes. There are usually no signs or symptoms of cardiovascular or central nervous system toxicity if the tourniquet is deflated at least 5 minutes after the drug is injected into the venous system, although tinnitus has been noted.⁵⁸

Approximately 70% of the administered lidocaine dose remains within the tissues of the isolated limb after tourniquet deflation.⁵⁶ The remaining 30% enters the systemic circulation during the ensuing 45 minutes.⁵⁶ **Much more local anesthetic is released from the tissues of the isolated limb into the circulation after tourniquet deflation if the limb is inadvertently exercised. This emphasizes the importance of maintaining the previously anesthetized extremity quiescent following tourniquet deflation.**

The other commonly used local anesthetic agent for IVRA, prilocaine, is associated with the formation of methemoglobin in 4 to 8 hours after administration.⁵⁵ Significant methemoglobinemia has not been reported when prilocaine has been used for IVRA. Prilocaine administered for IVRA has an onset of analgesia in approximately 11 ± 6.8 minutes.⁵⁹ Termination of analgesia following tourniquet deflation averages 7.2 ± 4.6 minutes.⁵⁹ The use of prilocaine for IVRA appears to be extraordinarily safe. There were no serious side effects or deaths reported by using this technique in one survey of 45,000 prilocaine blocks.⁶⁰ The effectiveness of prilocaine seems to be equivalent to lidocaine when used for IVRA.

Opioids can be administered in combination with local anesthetic agents for IVRA in an attempt to prolong analgesia following cuff deflation. Occasional side effects typically attributed to opioids given systemically may be noted following cuff deflation. These include nausea, vomiting, and mild sedation.^{19,37}

Neuromuscular blocking drugs can be administered in conjunction with local anesthetic agents to improve conditions for patients undergoing fracture reduction. There have been no reports of significant complications due to this adjuvant.

Clonidine and dexmedetomidine, α-2-adrenoceptors agonists, can be administered to decrease tourniquet pain during IVRA. The side effects include sedation and hypotension due to systemic absorption of the medication with cuff deflation which may limit their clinical use.

An intact tourniquet system is absolutely essential for the successful performance of IVRA. Unintentional deflation of the tourniquet or the presence of an arteriovenous communication with an intact tourniquet may result in serious sequelae. The tourniquet may be a source of complications. It may result in discomfort or ischemic pain. Systemic hypertension can occur from prolonged tourniquet inflation. Equipment misuse or malfunction is an important and avoidable source of complications. An intact and functioning tourniquet may be associated with leakage of local anesthetic agents from a supposedly isolated extremity into the systemic circulation.^{52,61} Lower limb IVRA has almost a 100% incidence of local anesthetic leakage from beneath the tourniquet versus a 25% incidence for the upper extremity.⁶² The use of IVRA for lower extremity analgesia had an associated incidence of a poor-quality block in

almost 40% of patients in one prospective study.⁶³ Local anesthetic may leak past an apparently fully functioning cuff due to the interosseous circulation that is not affected by occlusion of muscles and soft tissues. The functional significance of this circulation has been recognized for almost 35 years. It does not appear to be a significant factor in the production of complications due to IVRA.⁶⁴

Tourniquet deflation after IVRA is associated with signs and symptoms of systemic local anesthetic toxicity ranging from mild central nervous system-related events (e.g., tinnitus and perioral numbness) to devastating cardiovascular collapse. These symptoms correlate with the local anesthetic concentrations in arterial blood and not to venous concentrations.^{51,65} Intermittent cuff deflation may effectively prolong the time to achieve peak local anesthetic arterial concentrations but may not be entirely reliable in minimizing toxicity due to release of local anesthetic into the circulation.⁵¹ **Do not deflate the tourniquet for at least 10 minutes, and for greater safety 30 minutes, from the time the local anesthetic is injected into the isolated venous system.**

Another complication of IVRA is tourniquet pain which commonly occurs.⁵² We recommend the use of a tourniquet for any procedure performed under IVRA expected to last longer than 30 minutes.

There are very rare and isolated reports of neurologic complications associated with IVRA that include damage to the median, ulnar, and musculocutaneous nerves.⁶⁶ The etiology of such complications appears to be direct pressure from the tourniquet. These nerves subsequently exhibit histologic changes resembling crush injuries. It is recommended that the tourniquet time not exceed 2 hours to reduce the likelihood of capillary and muscle damage secondary to tissue acidosis.^{66,67}

A compartment syndrome may rarely occur following IVRA. This is especially true when IVRA is used for reduction of long bone lower extremity fractures. It may be due to the large volume of anesthetic injected to effect analgesia and inadequate (i.e., incomplete) exsanguinations of the limb prior to performing the block.^{68,69} A compartment syndrome has resulted from the inadvertent injection of hypertonic saline solution instead of local anesthetic solution.⁷⁰ One case report of a compartment syndrome resulted in the amputation of an arm in a patient who experienced thrombosis of the radial and ulnar arteries following IVRA after a relatively brief tourniquet occlusion time.⁷¹ Whether this resulted from unsuspected intraarterial injection of drug, a drug administration error, or perhaps an idiosyncratic drug reaction is purely speculative.

SUMMARY

IVRA is a valuable adjunct to the armamentarium of Emergency Physicians dealing with the acutely injured patient. The simplicity of the technique and the relative safety if strict adherence to the previously listed rules is maintained make it an attractive alternative to a brachial plexus block, spinal block, or epidural block. Simply being able to identify a peripheral vein, secure intravenous access, and use a pneumatic tourniquet makes this one of the most user-friendly regional anesthetic procedures. One of the only potential downsides to IVRA is the very finite duration of anesthesia and the inability to prolong analgesia into the postoperative or postprocedural period. This procedure can safely be performed in the Emergency Department.^{8,72,73}

Nitrous Oxide Analgesia

Rene Ramirez and Leann Mainis

INTRODUCTION

Nitrous oxide (N_2O) has been used for more than 150 years in medical practice for its anesthetic, analgesic, and anxiolytic properties. Its ease of use, ability to be combined with or used in conjunction with other medications, relative low cost, rapid onset, and rapid elimination have likely contributed to nitrous oxide remaining one of the most commonly used anesthetics for medical and dental purposes.^{1,2}

Joseph Priestly synthesized nitrous oxide in 1772 shortly after his discovery of oxygen. Humphry Davy was the first to identify the analgesic and anesthetic effects of nitrous oxide in 1799 and was the first to coin the term "laughing gas."¹ It remained largely a recreational drug for approximately 40 years despite noting its analgesic effects and predicting surgical applications. An American Dentist by the name of Horace Wells demonstrated clinical anesthesia for the first time in 1845 at Massachusetts General Hospital by using nitrous oxide and having one of his own teeth extracted. It was later recognized that the concentrations needed for anesthesia jeopardized patients because of their potential to cause hypoxia and lead to death.¹ Edmund Andrews added oxygen to the nitrous oxide mixture in 1868 to prevent the hypoxia that was commonly seen with the use of nitrous oxide. The first detailed analysis of nitrous oxide-oxygen mixtures as they apply to pain relief of angina without sedation or hypoxia was published by Stanislav Klikovich in 1881. In 1934, a self-administered apparatus of nitrous oxide with air was introduced to facilitate childbirth.³ Seward improved on the self-administered apparatus in 1949 by adding oxygen instead of air to the nitrous oxide for a more prolonged analgesia and sedation during childbirth without the possibility of inducing hypoxia.⁴ Ruben completed a study in 1969 of more than three million patients receiving nitrous oxide without a mishap.⁵ Nitrous oxide has gained widespread acceptance since then and is the most frequently used inhalational anesthetic agent. It is used in conjunction with a volatile anesthetic gas since it only possesses weak anesthetic properties. Nitrous oxide has been used experimentally in animal models after resuscitation. It has been shown to offer global neuroprotection due to its blockade of the N-methyl-D-aspartate (NMDA) receptor in the brain.⁶

Nitrous oxide-oxygen mixtures were first applied in an ambulatory setting in 1955. Dentists in Denmark used them for office-based procedures. A 50:50 mixture of nitrous oxide with oxygen (Entonox, Linde Healthcare Inc., Worsley, Manchester, United Kingdom) has been used by the British Ambulance Service in a self-administered format since 1970.⁷ Nitrous oxide-oxygen mixtures became popular in the United States as a sedative and analgesic for use in the Emergency Department during the late 1970s.⁸

ANATOMY AND PATHOPHYSIOLOGY

Nitrous oxide is a colorless gas at room temperature. It has a pleasant slightly sweet odor and taste. Nitrous oxide is heavier than air and non-inflammable. **It is combustible when mixed with oxygen.** Nitrous oxide is poorly soluble with a high minimum alveolar concentration (MAC) value and is 34 times more soluble in plasma than nitrogen. It diffuses rapidly across biologic membranes into the bloodstream (e.g., lung-blood and blood-central nervous system). It results in a rapid onset in 30 to 60 seconds and has a short duration of action. Maximum effect occurs at approximately 2 minutes. Its duration of action lasts 2 to 5 minutes after administration is discontinued. **Nitrous oxide does not have significant cardiovascular or respiratory depressant effects. Nitrous oxide maintains protective airway reflexes when inhaled at levels below 50% and does not require fasting or postprocedure monitoring.**⁹⁻¹¹ Cortical function is depressed quickly after the start of administration which decreases all sensory input (i.e., hearing, pain, smell, taste, temperature, and touch).

Nitrous oxide displaces nitrogen and increases the volume of gas in body cavities (e.g., the gastrointestinal tract, middle ear, pleural spaces, and sinuses). It will result in an increased pressure within these confined spaces. Nitrous oxide is lipid insoluble resulting in minimal uptake by fat, muscle, and solid organs. **It has no excretion products and is eliminated unchanged through the lungs.** This makes it useful in patients with liver or kidney disorders.

Nitrous oxide acts supraspinally to induce analgesia by activation of opioidergic neurons in the periaqueductal gray matter and non-adrenergic neurons in the locus ceruleus of the brainstem.¹²⁻¹⁴ This leads to disinhibition or activation of the descending noradrenergic inhibitory pathways via inhibition of γ -aminobutyric acid (GABA) interneurons. This results in a negative modulation of the nociceptive processes at the spinal cord level.¹⁵ The predominant theory of the molecular mechanism to account for nitrous oxide's anesthetic action is a noncompetitive inhibition of the NMDA subtype of excitatory glutamate receptors.¹⁶

Nitrous oxide has the five actions of mild sedation, anxiolysis, mild to moderate analgesia, weak anesthesia, and mild dissociative effects.¹⁷ Nitrous oxide has been shown to be effective in 85% of cases involving mild to moderate pain.¹⁸ Nitrous oxide does not require intravenous (IV) access, a feature highly desirable by most patients. **The agent is a more potent anxiolytic than analgesic.** Anxiolysis is obtained by inducing a state of euphoria with a concurrent mild sedating effect. The analgesic effect is a result of an increase in the pain threshold. Inhalation of a 50:50 nitrous oxide-oxygen mixture has been reported to produce analgesia equivalent to 10 to 20 mg of morphine; however, its effects are highly variable.^{8,19} **Combination therapy for painful procedures with an analgesic is often required due to its relatively weak analgesic effects.**²⁰ One example is that the infiltration of a local anesthetic solution for laceration repair is more tolerable under the use of nitrous oxide. Nitrous oxide may be used to decrease the dose of local anesthetic required for the procedure.

Nitrous oxide used in an ambulatory care setting (e.g., Emergency Departments and Dental Offices) is usually mixed with oxygen in

a 50:50 mixture. The percentage of nitrous oxide is titrated up or down. Nitrous oxide becomes a more effective general anesthetic when concentrations exceed a 50:50 mixture. **Hypoxemia is a concern at general anesthetic doses.** The nitrous oxide-oxygen ratio must be adjusted for altitude due to a lower atmospheric pressure and a lower partial pressure of the gas. A 70:30 ratio of nitrous oxide to oxygen was effective in Denver with an elevation of 5000 feet.²¹ The sex of the patient does not influence the response to nitrous oxide administration.²¹

Nitrous oxide is easy to obtain and usually requires no age limit to purchase. It can be purchased from head shops, kitchen stores, and the Internet. It is also available in balloons. It is highly abused by young individuals.²²⁻²⁵ Users often binge frequently with nitrous oxide. Its effects are short-lived. Nitrous oxide is used in kitchen gadgets used to produce whipped cream, other whipped agents, and foams (**Figure 158-1A**). Rechargeable units of nitrous oxide are sold as whippets (**Figure 158-1B**) for use in kitchen gadgets. The whippets are abused. Nitrous oxide is the propellant in cans of whipped cream and other food substances. These items are purchased for abuse (**Figure 158-1C**). Automotive kits of nitrous are sold to boost a car's performance (**Figure 158-1D**). Abuse of nitrous oxide for euphoria can result in permanent neurologic deficits or death.²⁶

INDICATIONS

Nitrous oxide is an attractive agent for procedural sedation due to its rapid onset and offset of sedation.²⁷ Nitrous oxide has been used by many types of medical and dental practices.² Nitrous oxide-oxygen mixtures have been shown to be effective in both the Emergency Department and the prehospital setting to alleviate anxiety and control mild to moderate pain. The indications for nitrous oxide use are reserved for patients with mild to moderate pain, who are anxious, or who will undergo a painful procedure. It has been useful in abscess drainage, angina pain, dental procedures, foreign body removal, fracture reduction, laceration repair, lumbar puncture, migraine, urethral catheterization, vascular access, and wound debridement.^{19,27-35} A concentration of 70% nitrous oxide for 3 minutes can reduce venipuncture pain.³⁶ It can be used as an alternative to opioids.³⁷ A more detailed list of the uses of nitrous oxide is contained in **Table 158-1**.

CONTRAINDICATIONS

There are few contraindications to the use of nitrous oxide (**Table 158-2**).² Do not administer nitrous oxide to patients with significant respiratory compromise or heart failure requiring higher oxygen levels. **Normal cognitive function is required for its safe and effective use when using a self-administered nitrous oxide system.** Exclude patients with altered consciousness, head injuries, or the inability to understand instructions for administration. Children younger than 4 years of age cannot properly follow the instructions for the use of the system. Hysterical patients, somnolent patients, and those with altered mental status cannot comprehend and follow the instructions for the proper use of the system.

Nitrous oxide rapidly crosses membranes and exchanges with nitrogen. **Patients with risks for a closed nitrogen-containing space injury are not eligible candidates.**³⁸ This includes patients with an air embolism, bowel obstruction, emphysema, middle ear surgery, pneumocephalus, pneumoperitoneum, or a pneumothorax. **Rapid diffusion of nitrous oxide into a closed gas-containing space and its inability to leave the space quickly result in an increased volume of the space and an increased pressure within the space.** Patients may have intraocular gas bubbles placed in their eye by an Ophthalmologist in the management of retinal diseases.

FIGURE 158-1. Common nitrous oxide-containing devices are available to the public. **A.** Kitchen gadgets. **B.** Small charges of nitrous oxide or whippets. **C.** Huffing of nitrous oxide from whipped cream cans. (Photo courtesy of Cortland Preventive Services, New York, NY.) **D.** An automotive kit to boost performance.

These gas bubbles may persist for several months in the eye. Exposure to nitrous oxide can cause rapid expansion of these gas bubbles and may lead to blindness.³⁹ Exclude patients with decompression sickness or undergoing hyperbaric oxygen therapy.

Nitrous oxide oxidizes cobalamin and inactivates vitamin B₁₂.^{38,40} Vitamin B₁₂ is a cofactor of methionine synthetase and is an enzyme in folate and methionine metabolism.⁴¹ Patients with methionine synthetase deficiency will have bad outcomes with nitrous oxide exposure. Inactivation of methionine synthetase is associated with increased plasma homocysteine concentrations which may increase the risk of postprocedural cardiovascular complications.⁴² Nitrous oxide irreversibly inhibits deoxyribonucleic acid (DNA) synthesis.⁴³ Other inborn errors of metabolism that can result in serious outcomes when nitrous oxide is administered include homocystinuria and methylmalonic acidemia.⁴⁴ Patients with a vitamin B₁₂ deficiency or an acquired vitamin B₁₂ deficiency (e.g., resection of the terminal ileum or pernicious anemia) can develop leukopenia,

megaloblastic anemia, or myeloneuropathy after receiving nitrous oxide.^{38,45} Relative contraindications to the use of nitrous oxide include first-trimester pregnancy, myocardial ischemia, anesthesia over 6 hours, and pulmonary hypertension.⁴⁶

EQUIPMENT

- Nitrous oxide tank
- Oxygen tank
- Mixing valve
- Scavenging device
- Demand valve apparatus
- Nasal mask
- Face mask
- Sensor to measure ambient levels of nitrous oxide

TABLE 158-1 Some of the Indications for Nitrous Oxide Administration

Acute pain	Joint dislocation reduction
Anginal chest pain	Joint injections
Anxiety relief	Labor pain
Biliary colic	Laceration repair
Bladder catheter insertion	Laser procedures
Burn care	Migraine headache
Cerumen impaction removal	Minor gynecologic procedures
Cervical and uterine procedures	Minor surgical procedures
Chronic pain	Musculoskeletal trauma
Cluster headache	Nasal surgery
Colonoscopy/sigmoidoscopy	Pancreatitis
Cystoscopy	Pelvic and physical examinations
Delivery/labor pain	Prehospital analgesia
Dental procedures	Renal colic
Dilation and curettage	Sickle cell pain crisis
Dressing changes	Tube thoracostomy
Foreign body removal	Vaginal examinations
Fracture reduction	Wound care
Incision and drainage of cysts or abscesses	Zipper entrapment
Intravenous access	

- Pulse oximeter
- Cardiac monitor
- Supplemental oxygen source
- IV catheters, tubing, and fluid
- Analgesic agents
- Anxiolytic-sedative agents
- Resuscitation equipment

A typical hospital-based device applicable for Emergency Department use is shown in **Figure 158-2**. The mixing valve ensures that a constant ratio or mixture of oxygen and nitrous oxide is delivered to the patient. The sources for the nitrous oxide-oxygen mixture can be individual cylinders or wall units. The device has a fail-safe mechanism that automatically stops gas flow when either source becomes empty.⁴⁷ The unit provides automatic oxygen enrichment at very shallow breathing rates.

TABLE 158-2 Contraindications to the Use of Nitrous Oxide

Abdominal pain of unknown etiology	Immunosuppression
Acute myocardial infarction	Inability to follow or understand instructions
Air embolism	Inner ear pain
Alcohol intoxication	Intoxication (alcohol or drugs)
Altered consciousness	Maxillofacial trauma or injuries
B ₁₂ deficiency	Methionine synthetase deficiency
Bowel obstruction	Methylmalonic acidemia
Chest trauma (blunt or penetrating)	Middle ear surgery
Chronic asthma	Overdoses
Chronic bronchitis	Pneumocephalus
Chronic obstructive pulmonary disease	Pneumoperitoneum
Congestive heart failure	Pneumothorax
Decompression sickness	Pregnancy, except labor
Drug ingestions	Psychiatric patients
Early pregnancy	Pulmonary edema
Emphysema	Respiratory compromise
Facial trauma	Shock
Folate deficiency	Small bowel obstruction
Head injuries	Treatment with bleomycin sulfate
Hollow viscus perforation	Unable to follow instructions
Homocystinuria	Unable to self-administer gasses
Hypotension	Young children
Hypoxemia	

It is required by the National Institute of Occupational Safety and Health (NIOSH) to have a sensor to monitor ambient levels of nitrous oxide within the treatment area. The scavenging device reduces the ambient levels of nitrous oxide within the treatment area. Elevated levels of nitrous oxide have been associated with a decreased fertility rate, an increased rate of spontaneous abortion, and neurologic disturbances among Dental Assistants.⁴⁸ Ambient levels of nitrous oxide were measured and noted to be 500 ppm after 8 minutes of patient administration.⁴⁹ The ambient levels in a similarly sized room were 0 when a scavenging device was used.⁵⁰

Portable handheld units are available for use in clinics and ambulances (**Figure 158-3**). Many of these units are being used. Several companies have developed portable units. The nitrous oxide levels will vary in an ambulance with the airflow within the patient compartment. Trace levels of the gas are reduced to safe levels without the use of a scavenging device if the air-conditioning system or fans are operating and the ambulance is in motion.⁵¹

Entonox (Linde Healthcare Inc., Worsley, Manchester, United Kingdom) is a pre-prepared 50:50 mixture of nitrous oxide and oxygen. It is supplied in blue cylinders so it is not mistaken for another gas. It is quite popular with prehospital care providers due to its compact size and light weight. The main drawback is that only a fixed concentration of nitrous oxide can be administered. Oxygen is heavier than nitrous oxide. Invert the tank several times prior to use to mix the contents as the gasses can separate in cold weather. The patient can receive a higher concentration of oxygen at the start of using the tank and a higher concentration of nitrous oxide toward using the end of the tank if it is not inverted several times before use. This formulation of nitrous oxide is not currently approved for use in the United States by the Food and Drug Administration (FDA).

A face mask or nasal mask connected to a demand valve will help minimize the unwanted release of nitrous oxide into the treatment area (**Figure 158-4**). Use a nasal mask for procedures in and around the mouth. The face mask is more effective for pediatric patients (personal communication from M. Civitello, Porter Instruments). Dental offices usually use nasal masks without demand valves (personal communication from M. Civitello, Porter Instruments). The demand valve allows for the self-administration of the gaseous mixture. A negative inspiratory flow of -1 to -5 cmH₂O must be generated to activate the gas flow. An airtight seal is required between the patient's face and the mask to achieve a negative inspiratory flow. **The demand valve provides for a safe administration of nitrous oxide, minimizes the risk of oversedation, guards against human error, and protects against equipment failure. This demand valve system makes overdose almost impossible. The patient will be unable to hold the mask in position, will drop the mask, and will inhale room air as their level of consciousness declines.**

Many commercially available nitrous oxide administration devices do not have a demand valve and allow the nitrous oxide concentration to be adjusted from 0% to 70%. The advantages of these devices are the ability to control the percentage of nitrous oxide delivered and to make any adjustments based on the clinical situation. These devices have numerous disadvantages. The Emergency Physician must monitor the patient much more closely for the effects of hypoxemia, oversedation, and sedation. This requires the Emergency Physician to adjust the settings during the procedure for which the nitrous oxide is being used. **The lack of a demand valve can result in oversedation. The free flow of the nitrous oxide through the mask when the patient releases it results in increased concentrations in the procedure room which can affect the health care personnel.**

The INOmax DSIR Plus was developed for use in magnetic resonance imaging (MRI) rooms (Mallinckrodt, Dublin, Ireland) (**Figure 158-5**). It is often used in pediatrics to reduce pulmonary

FIGURE 158-2. An example of a nitrous oxide machine. (Photo courtesy of Porter Instruments, Hatfield, PA.)

hypertension. This usually requires the patient to temporarily discontinue nitrous oxide therapy while they go to be scanned. This can result in an increase in pulmonary artery pressure and hypoxemia. The device can be used with MRI-compatible ventilators to continue the administration of nitrous oxide. It can also be used for the temporary sedation of patients receiving an MRI.

PATIENT PREPARATION

Inform the patient and/or their representative of the risks, benefits, potential complications, and alternatives to nitrous oxide anesthesia. Obtain a signed informed consent for the nitrous oxide anesthesia in addition to the consent for the procedure for which nitrous oxide is being administered. Establishing IV access for nitrous oxide administration is not required but is recommended. An IV can be

A

B

obtained after beginning the nitrous oxide administration to make the pain of catheter insertion much more tolerable. Apply noninvasive cardiac monitoring leads, a noninvasive blood pressure cuff, and pulse oximetry to the patient. Place the patient supine on a gurney

A

B

FIGURE 158-4. Self-administration of nitrous oxide. **A.** Use of a face mask. **B.** Use of a nasal mask. (Photos courtesy of www.thedrugclassroom.com.)

or sitting in a procedure (e.g., dental) chair that reclines. Preoxygenate the patient for 2 to 3 minutes with 100% oxygen. **Encourage the patient to remain calm and breathe in a controlled manner with special emphasis not to breathe too deeply or rapidly.**

TECHNIQUE

The nitrous oxide-oxygen gas mixture must be administered by appropriately licensed individuals, or under the direct supervision thereof, by state law. The Emergency Physician responsible

for the treatment of the patient and/or the administration of the nitrous oxide-oxygen gas mixture must be trained in the use of the agents, the techniques to administer nitrous oxide, and the appropriate emergency response in the rare case of respiratory compromise.

Prepare the machine. A flow rate of 4 to 6 L/min of nitrous oxide is generally appropriate for most patients. Begin with 2 minutes of 100% oxygen followed by a 40% nitrous oxide mixture (i.e., 4 L/min of nitrous oxide and 6 L/min of oxygen). Increase the nitrous oxide in 10% intervals until the desired clinical effect and a maximum of

FIGURE 158-5. The INOmax DSIR Plus system nitrous oxide machine. (Photo courtesy of Mallinckrodt.)

70% nitrous oxide (i.e., 7 L/min of nitrous oxide and 3 L/min of oxygen). Most systems do not allow over 70% nitrous oxide to be administered. The concentration of nitrous oxide should not routinely exceed 50% during the administration. Titrate the nitrous oxide concentration to the clinical situation. It may be decreased during less painful procedures and increased during more painful procedures. **It is important to continuously monitor the patient's respiratory rate and level of consciousness during the procedure.**

The nitrous oxide-oxygen gas mixture can be administered via a nasal mask or a face mask. The nasal mask is used primarily by Dentists. It has been shown to be more effective in pediatric patients and patients undergoing procedures around the mouth and chin. The size and positioning of the nasal mask are important for ensuring a snug fit. Encourage the patient to breathe through their nose as opposed to their mouth in a controlled manner (i.e., not too fast or too deep).

The demand valve in the face mask system prevents gas flow unless a negative inspiratory pressure is applied with a self-administered face mask. The gas flows constantly if a demand valve is not used. The patient applies the face mask, ensuring an airtight seal that covers both the mouth and nose (**Figure 158-4A**). Do not remove the face mask between breaths unless adverse effects are noted (e.g., dysphoria, headache, lightheadedness, nausea, vertigo, and vomiting). Remove the mask and administer 100% oxygen via a non-rebreather mask for 5 minutes or until the adverse symptoms resolve. The analgesic effects of nitrous oxide are commonly noted within 90 to 120 seconds of the onset of administration.⁵² The patient becomes mildly sedated in 3 to 5 minutes. Supplemental analgesics (e.g., wound infiltration of a local anesthetic) may be administered as needed or the procedure can be performed.

It is difficult for a patient to overdose on nitrous oxide if the mask is not secured to their face with tape or a strap. The patient will often remove the hand and the mask from their face as a state of analgesia and euphoria develops. The mask will fall off or loosen if the seal is not maintained. The demand valve will not be triggered if the mask falls off the patient's face. If not using a demand valve, the gas flows into the room and not directly into the patient. **It is extremely important not to secure the mask to the patient's head with straps or tape so that nitrous oxide delivery will cease as the patient falls asleep.** The patient may reapply the mask and self-administer additional nitrous oxide upon awakening or experiencing pain. **It is extremely important to note the need for proper ventilation and/or a nitrous oxide scavenging system.** Nitrous oxide can build up in the treatment area affecting others aside from the intended patient without proper ventilation and/or scavenging.

Remove the face mask upon completion of the procedure. Administer 100% oxygen for 5 minutes. This increases the rate of elimination of nitrous oxide and minimizes the side effects (e.g., dizziness, dysphoria, headache, lightheadedness, nausea, and vomiting).⁵³ Record the amount of gas and the duration of time used in the patient's chart. Record this information in the log maintained with the nitrous oxide device. Clean the demand valve apparatus, if used, prior to and after each administration.

PEDIATRIC CONSIDERATIONS

The previously described preparation and technique apply to the pediatric patient with a few differences.^{2,54-56} Explain how the gas works to the patient. Show the child the equipment and let them handle it to realize it is not scary. Demonstrate the use of the mask on yourself and the parent before demonstrating it on the child. A face mask is preferred over the nasal mask for young children as it is difficult for them to cooperate with not mouth breathing. The young child may have difficulty following instructions or using the

face mask. Apply a flavored scent or flavored lip balm to the inside of the mask to make it more inviting for the child to use. A trained health care provider other than the Emergency Physician (e.g., another Emergency Physician, Nurse, Nurse Practitioner, Respiratory Therapist, or Physician Assistant) may be required to administer the nitrous oxide. This second provider can help hold the mask over the child's face and monitor the level of sedation to prevent oversedation. Concentrations up to 70% can be safely used.⁵⁷

ASSESSMENT

Ensure that the patient is experiencing adequate analgesia before performing the procedure for which nitrous oxide is administered. Nitrous oxide analgesia is supposed to be the equivalent of administering 10 to 20 mg of morphine. Real use has shown that patients experience a wide range of pain relief (e.g., none, mild, moderate, or marked). Nitrous oxide administration may require supplementation with parenteral analgesics, parenteral sedatives, or other anesthetic techniques.

AFTERCARE

There is no aftercare related to the administration of nitrous oxide anesthesia other than 5 minutes of supplemental 100% oxygen via a nonrebreather mask. Continue to monitor the patient until they return to their pretreatment level of responsiveness. This often takes less than 10 minutes in almost all patients.

COMPLICATIONS

The side effects of a 50:50 nitrous oxide-oxygen mixture are relatively mild. Lightheadedness is most common with the occasional patient complaining of paresthesias or nausea. Donen and colleagues reported a 19% incidence of dizziness, lightheadedness, or vertigo; 4% incidence of paresthesias, headache, or amnesia; 5% incidence of nausea; and 1% incidence of vomiting.⁷ Other reported side effects include abdominal pain, agitation, chest pains, desaturations, fatigue, hallucinations, hiccups, hyperventilation, irritability, and pallor.²⁷ **There is little to no risk of inducing anesthesia or losing protective reflexes if used in concentrations of 50% or less.** Commonly used procedural sedation medications (e.g., ketamine and propofol) have been associated with laryngospasm. It was previously thought that nitrous oxide did not have the need for advanced airway support in concentrations up to 70% and was not associated with laryngospasm.²⁷ The first known case report of laryngospasm associated with nitrous oxide was published in 2015.⁵⁸ **It is important when using any procedural sedation medication to always have advanced airway equipment readily available.**

The concept of diffusion hypoxia was first described by Fink in 1955.⁵⁹ He noted that the rapid diffusibility of nitrous oxide could displace oxygen from the alveoli after discontinuation of the gas.⁵⁹ This concept has led to the administration of 100% oxygen for 5 minutes following the nitrous oxide administration. There has been evidence to disprove diffusion hypoxia in low-dose nitrous oxide mixtures (e.g., 50:50 nitrous oxide-oxygen). It is only a legitimate concern at higher concentrations used during general anesthesia. **The use of 100% oxygen following the cessation of nitrous oxide is still suggested.** Caution is advised in patients with chronic obstructive pulmonary disease in whom the increased oxygen concentration found in the nitrous oxide-oxygen mixture can potentially depress the respiratory drive.

There has been growing concern regarding the safety of trace levels of nitrous oxide in the Operating Room, Emergency Department, and Dentist office.⁴⁷ Always use nitrous oxide in a well-ventilated treatment room. There is evidence to show that elevated levels of

nitrous oxide are associated with miscarriages, reduced fertility, and increased cervical cancer rates among female Dental Assistants.^{1,48} Scavenging devices help reduce the ambient levels of nitrous oxide within treatment areas.^{47,60} The demand valve system allows for all exhaled gases to escape into the surrounding environment without a scavenging device. A scavenging device will collect the exhaled gas and remove it from the patient care area.⁵⁰ Scavenging devices can maintain ambient levels of nitrous oxide below 1200 ppm by the guidelines proposed by NIOSH.⁶¹ Nitrous oxide levels above 1200 ppm are considered a hazardous condition. Scavenging systems combined with air conditioning are considered the most effective means of lowering ambient nitrous oxide levels.⁶²

There has been concern raised about the experimental use (i.e., abuse or diversion) of nitrous oxide gas by medical personnel. Prepare a strict protocol on the use of nitrous oxide and its associated demand valve apparatus prior to the implementation of nitrous oxide-based procedural sedation in the Emergency Department. Record the volume of gas administered in the patient's chart as well as in a log kept with the nitrous oxide device following each use of nitrous oxide. The demand valve apparatus can be safely secured in the narcotic cabinet or within a Pixis system until it is required for patient use.

There has been concern about the effects of nitrous oxide on the hematologic, immunologic, myocardial, neurologic, and reproductive systems. Nitrous oxide has been associated with anemia, birth defects, decreased neutrophil chemotaxis, decreased proliferation of mononuclear cells, increased spontaneous abortions, impaired wound healing, megaloblastic anemia, myocardial ischemia, polyneuropathy, reduced fertility, subacute combined neurodegeneration of the spinal cord, and thrombocytopenia.^{24,25,40,44,63-69} Nitrous oxide-induced neurotoxicity has been implicated in the development of long-lasting cognitive deficits when administered to patients of extremes of age.⁷⁰

SUMMARY

The use of a nitrous oxide-oxygen mixture has been shown to be safe, effective, and easy to administer in an ambulatory care setting. The gas provides rapid onset of sedation, hypnosis, and rapid offset. It is a mild anesthetic that helps to facilitate the performance of mild to moderately painful procedures. The adverse effects are minimal. The nitrous oxide gas is usually self-administered. Concerns of hemodynamic compromise are negligible. The use of nitrous oxide in a closed-space environment should be accompanied by a scavenging device to minimize ambient levels of the gas.

Procedural Sedation and Analgesia (Conscious Sedation)

Hagop M. Afarian

INTRODUCTION

Procedural sedation and analgesia (PSA) techniques are an essential skill for any Emergency Physician. The daily practice of Emergency Medicine employs painful and anxiety-provoking measures to perform diagnostic testing or therapeutic interventions. PSA is a skill that may require a credentialing process at some institutions. It probably has evoked a written procedural guide in most hospitals and Emergency Departments, with or without the input from a hospital-wide PSA committee or the Department of Anesthesiology. PSA certification may require annual competency assessments in the form of a written examination or practical scenarios. PSA is a technique that probably receives a great deal of attention from the continuous quality improvement committee because of The Joint Commission's directive. It is a skill that, with proper training and well-designed application principles, will provide the patient and their families with a sense of compassion and caring for their physical and emotional distress.^{1,2} PSA is a skill that may result in horrific outcomes when performed without anticipation of complications, appropriate training, knowledge, and risk-benefit analysis.³

An extensive spectrum of painful and anxiety-provoking clinical presentations is seen in an Emergency Department on any given day. There may be a dislocation reduction, a fracture reduction, a diagnostic lumbar puncture, a sexual assault examination on a child, or neuroimaging on a combative, head-injured patient. Each presentation has a separate subset of variables to consider prior to PSA. While Anesthesiologists are still considered the "experts" in sedation, they are not readily available to the Emergency Department's beck and call. Multiple guidelines for the use of PSA account for these limitations and are followed to ensure that safe effective care can be rendered to their patient populations.⁴⁻¹⁰

The environment of the Emergency Department is unique in many facets of PSA with situations being nonelective. Procedures are relatively brief and make Operating Room time neither timely nor cost effective. Intrinsic to PSA is the core training and frequent exposure. Who better to handle an untoward cardiopulmonary complication of a procedure than a specialist of airway management and resuscitation?

It is critical to the technique of PSA, including drug selection, to take a variety of parameters into consideration before the first medication is administered.¹¹ The potency and effectiveness of today's agents are a double-edged sword. They are invaluable with the correct selection and administration.³ They are a recipe for disaster if risks are not appropriately identified and minimized.

Monitoring techniques (e.g., pulse oximetry and capnography) are effective adjuncts to procedural monitoring. They are no substitute for a trained and dedicated observer.

TERMINOLOGY

Textbooks and review articles use various definitions to define components of PSA, formerly known as conscious sedation.¹² Terms such as light and deep sedation are often applied to the extremes of the sedation continuum. **The important thing to realize is that sedation is a continuum.**^{5,13} At the far left of the continuum is the alert and anxious patient. Eye opening, speech, and motor responses diminish as the sedation process proceeds. At the opposite end of the spectrum are CO₂ retention, hypoxia, hypotension, and finally death. These later endpoints are obviously not desirable. Anxiolysis and analgesia are other terms that need definition. The following terminology is representative of current PSA jargon.

Analgesia equates to pain relief without alteration in mental status. Analgesia is required in a variety of procedures in which painful manipulation or instrumentation is anticipated. Most potent pain medications will also have a component of sedation, especially the opioids. **The sedation component needs to be carefully considered during drug selection and dosing calculations to minimize the risk of overshooting the desired sedation endpoint.**

Anxiolysis means to relieve apprehension. Patients may be anxious for any variety of reasons besides the thought of a painful forthcoming procedure. Anxiolysis involves allaying the patient's fears. **The agents used for anxiolysis are pure sedatives and provide no pain relief.** Although some degree of sedation is to be expected, it should be minimized with appropriate drug and dosing selection.

Sedation blunts the patient's perception of the surroundings and pain with a depression in their state of wakefulness. Levels of procedural sedation do not follow a discrete stepwise progression. Sedation proceeds along a continuum ranging from a mild sedation through deep sedation into general anesthesia. The level of sedation is determined by a patient's state of anxiety, mobility, retention of protective reflexes, and wakefulness.

Dissociative sedation implies sedation, analgesia, amnesia, and the induction of a cataleptic state. This state preserves ventilatory drive and maintains protective reflexes while maintaining cardiovascular stability. **Ketamine is the primary agent used to induce this state.**

Neurolepsia is a reduced motor activity state in which the patient has reduced anxiety and indifference to their surroundings. Neurolepsia is best achieved with major tranquilizers (e.g., droperidol or haloperidol). Its application is best suited to the agitated or violent patient whose behavior places their self or others at risk for harm.

General anesthesia represents the extreme right of this continuum. The patient has no awareness of the environment and has lost the ability to self-maintain protective reflexes. **This is not a desirable endpoint during PSA in the Emergency Department.**

PSA is a technique of administering sedation or dissociative agents with or without analgesics to induce a state that allows the patient to tolerate unpleasant procedures while maintaining cardiorespiratory function. PSA produces a depressed level of consciousness which allows the patient to maintain airway control independently and continuously. The medications, doses, and techniques used are not likely to produce a loss of protective reflexes according to the American College of Emergency Physicians Clinical Policy for PSA in the Emergency Department.⁴

Standardizing levels of sedation along a continuum has been attempted with various scoring systems.¹⁴ The Ramsay scale was specifically devoted to providing objective determinations of

TABLE 159-1 The Ramsay Scale for Standardized Levels of Sedation⁴

Level	Clinical status	Sedation equivalent
1	Awake, anxious, agitated	None
2	Awake, cooperative, oriented, and tranquil	Anxiolysis
3	Awake, responds to commands only	Mild sedation
4	Asleep, responds to brisk stimuli	Moderate sedation
5	Asleep, sluggish response to stimuli	Deep sedation
6	Asleep, no response to stimulation	Anesthesia

sedation during drug-induced sedation practices. Scoring consists of six sequential scoring levels (Table 159-1).

Another scoring system is the Observer's Assessment of Alertness/Sedation (OAA/S) Scale. It was designed as a research tool for studies incorporating pharmacologic studies with benzodiazepines.¹⁴ The scoring system was based upon the assessment of the patient for facial expressions, ocular appearance, responsiveness, and speech. The OAA/S Scale incorporates the patients' responsiveness to the effects of the agents given in contrast to the similar observational scoring used in the Ramsay scale.

INDICATIONS

A wide variety of clinical presentations and procedures would entail the appropriate use of analgesia, anxiolysis, dissociation, and sedation for case management (Table 159-2). PSA is particularly suited to pediatric patients requiring multiple painful procedures in the Emergency Department, especially if they can be done simultaneously or one after another. An example is the young child with a fever undergoing a septic work-up requiring lumbar puncture, urethral catheterization, and vascular access.

There are four goals of PSA. The first and foremost is to assure patient safety with a careful risk-benefit assessment and a well-defined clinical procedure to maximize benefit, limit risk, and foresee potential complications. Second is to appropriately assess and deliver adequate analgesia, anxiolysis, sedation, and amnesia as dictated by the patient's needs. Third is to consider the psychological impact of the forthcoming procedure and minimize the impact of these events. Fourth is to provide a fluid transition to the preprocedural physical and mental status while assuring a safe discharge and postprocedural observation.

TABLE 159-2 The Indications for PSA

Anxiolysis/mild sedation (analgesia minimal)	Pediatric dissociative sedation
Painless diagnostic studies, i.e., CT scanning	Multiple trauma procedures
Lumbar puncture	Fracture/dislocation reduction
Posterior nasal packing	Abscess incision and drainage
Pediatric foreign body removal	Paraphimosis reduction
Pediatric slit lamp examination	Complex facial lacerations
Mild sedation and analgesia	Tongue lacerations
Pediatric hand/finger injuries (with local analgesia)	Complex hand lacerations
Disimpaction	Burn debridement
Vaginal/rectal foreign bodies	Sexual assault examination
Moderate sedation and analgesia	Adult dissociative sedation
Traction splints for fractures	Asthma intubation
Burn debridement	Trauma resuscitation
Cardioversion	Hemodynamic instability requiring sedation
Fracture/joint reduction	Lengthy and painful procedures
Deep sedation and analgesia	
Incision and drainage perineal/perirectal abscesses	
Complex pediatric lacerations	
Extensive road rash debridement	

CT, computed tomography.

CONTRAINDICATIONS

There are three contraindications to the use of PSA. A known allergy to the individual medication(s) being considered is an absolute contraindication. Ketamine and nitrous oxide have agent-specific contraindications. The lack of experienced or credentialed personnel is essential. PSA requires personnel appropriately trained in airway management. Appropriate monitoring capabilities must be available (e.g., equipment monitors and personnel to observe the monitors, record procedural flow, and monitor postprocedural recovery).

Issues such as the time of the last oral intake should be considered in the risk-benefit analysis. **A full stomach does not constitute an absolute contraindication to PSA.**¹⁵⁻¹⁷ Concomitant drug or alcohol use is a complicating variable that needs to be recognized and accounted for prior to the procedure. Complicated airway anatomy should receive attention in case emergent airway management is necessary.

EQUIPMENT

- Crash cart with resuscitation equipment
- Defibrillator
- Oxygen source
- Oxygen masks
- Nasal oxygen cannulas
- Oral airways
- Nasal airways
- Bag-valve-mask device
- Continuous pulse oximetry
- Capnography, if available
- Continuous cardiac monitoring
- Intravenous access supplies (Chapters 59 and 61)
- Suction source
- Suction catheters
- Pharmaceutical agents
- Reversal agents (i.e., naloxone and flumazenil)
- Succinylcholine
- Procedural supplies (e.g., suturing, splinting, etc.)

It is imperative that resuscitation equipment be immediately available prior to the onset of PSA. Make this requirement part of the preprocedural checklist. Age-appropriate equipment must be immediately available for children. The immediate availability of reversal agents is a prerequisite to the administration of opioids or benzodiazepines. Have succinylcholine readily available in case of laryngospasm or opioid-induced chest wall tightness.

PATIENT PREPARATION

INFORMED CONSENT

The issue of informed consent is institution specific (Chapter 1). Most institutions function under the premise that if a procedure has any significant level of risk inherent in its application, then informed consent regarding the risks and benefits of the procedure should be undertaken with the patient and/or their representative. The benefit to the patient is a careful calculated means at reducing the pain and anxiety associated with a planned diagnostic or therapeutic intervention. The risks are inherent in the medications selected, the patient's current physical condition, and complicating conditions (e.g., last meal, recent drug use, or recent alcohol use).

Explain the risks, benefits, and alternative procedures to the patient and/or their representative. Obtain an informed consent for the procedure and place this in the medical record. Obtain a separate informed consent for the procedure for which PSA is being performed.

PERSONNEL COMPETENCY AND CREDENTIALING

Any Emergency Physician practicing PSA must be competent in airway management and resuscitation.¹⁸ Competency credentialing is institution specific. Emergency Physicians may be granted privileges based on their residency training or current practice. Some institutions may mandate a written competency examination or advanced airway and resuscitation training (e.g., Advanced Cardiac Life Support certification).

Nursing personnel must be proficient in medication profiles, medication administration, and patient monitoring. The staff needs to be aware of policies and procedures. Competency testing may be a prerequisite to providing PSA. All personnel involved must meet these departmental and institutional requirements prior to initiation of PSA. More than one physician may be required for PSA in some complex cases, although there is no evidence to support dual-physician involvement for all cases.¹⁹

RISK-BENEFIT ASSESSMENT

The preprocedural assessment constitutes a risk assessment and a preprocedural baseline determination. Assessment requires a determination of the patient's current health and an evaluation of potential risk, adverse reactions, and procedural complications. The old adage "an ounce of prevention is worth a pound of cure" certainly applies with PSA. **Thorough preparation is critical to minimize patient risk.** Department procedural flowsheets, complete with preprocedural assessment checklists, can be a valuable adjunct.

Assign patients an American Society of Anesthesiologists (ASA) Physical Status Classification (**Table 159-3**).¹³ Emergency Department PSA would normally be limited to class I or class II patients. Class III or class IV patients are best served in consultation with an Anesthesiologist. Never perform PSA on class V patients.

Perform a complete history and physical examination prior to the application of PSA. Direct the emphasis toward allergies to any analgesic or sedation agent. Previous anesthesia and related complications may be critical to drug selection and/or the involvement of an Anesthesiologist. **Assess the patient's airway. Age-appropriate airway management equipment must be immediately available in the event airway control becomes necessary.** A patient's breathing is an important continuous determinate that needs to be observed and recorded before the procedure, throughout the procedure, and during recovery. Hypoventilation or bronchospasm may be clinically evident with observation before an alteration in heart rate or pulse oximetry is detected. **The patient's state of wakefulness and the ability to follow commands are markers for sedation.** A patient's mental status may be minimally depressed whereby they may respond to environmental stimuli whereas deep sedation requires moderate stimulation to arouse the patient.

TABLE 159-3 The American Society of Anesthesiologist's (ASA) Physical Status Classification

I.	Healthy patient
II.	Mild systemic disease—no functional limitation
III.	Severe system disease—definite functional limitation
IV.	Severe systemic disease—constant threat to life
V.	Moribund patient—not expected to survive without the operation

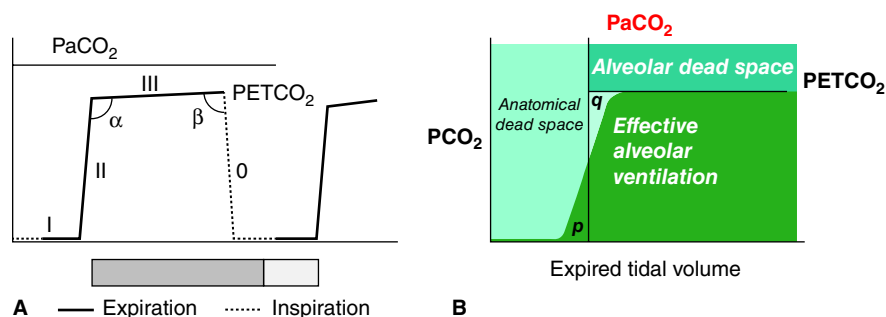

FIGURE 159-1. The capnogram. **A.** Segment, phases, and angles identified. **B.** The volume capnogram. The two triangles (i.e., p and q) are equal. The line divides the physiologic dead space into the anatomic dead space and alveolar dead space. (Used with permission from reference 119.)

A full meal less than 6 hours or liquids less than 2 to 3 hours prior to the procedure places adults at risk for aspiration if sedation inadvertently results in loss of protective airway reflexes. These time requirements are not a contraindication to the use of PSA. **Procedural sedation need not be delayed based on fasting time as there is no evidence to show decreased aspiration risk with any duration of fasting.**¹⁹ Agents used to promote gastric emptying or altering gastric pH to minimize the effects of aspiration are impractical in the Emergency Department due to their delayed onset for effectiveness. These procedures cannot usually be delayed due to the urgency of the matter.

Obtain baseline measurements of the patient's weight, blood pressure, heart rate, oxygen saturation, and capnography (if available). PSA can result in hypoxia and hypercapnia. The underlying mechanism is opioid-induced and sedative-induced hypoventilation. Pulse oximetry is routinely used during PSA. The degree of desaturation does not correlate alone with poor outcomes.²⁰ Capnography provides an early warning to a hypoventilatory condition and is the standard care in PSA.²¹ Oxygen application is considered routine, yet its value has not been established.²² The routine application of oxygen may delay recognition of a profound hypoventilatory state if capnography is not used.

The use of capnography is common practice in patients undergoing general anesthesia.²³ It is being used more routinely for PSA in the Emergency Department.^{10,24,25} Units come in small handheld models, bigger but portable models, and modules that attach to wall monitors. It numerically displays the exhaled CO_2 . The waveform shows the exhaled CO_2 concentration related to volume or time. The y-axis represents the partial pressure of expired carbon dioxide (PCO_2).

There is no evidence that capnography reduces serious adverse events during PSA. Capnography decreases the incidence of hypoxia and respiratory events.^{19,26} Capnography can identify respiratory depression early or that is undetected by the Emergency Physician.^{22,24,26-30} Evaluate the absolute end tidal CO_2 (ETCO_2) level or the ETCO_2 waveform to evaluate a patient's respiratory status.

The normal range for ETCO_2 is 35 to 45 mmHg. **Pulse oximetry measures oxygen saturation but not ventilation. The ventilation is often affected before oxygen saturation in respiratory decompensation.** A patient's oxygen saturation may not drop until late into their respiratory decline. **Direct observation of chest rise and respiratory rate is not sensitive to identify respiratory decompensation during PSA when compared to capnography.**^{31,32} **An $\text{ETCO}_2 > 50$ mmHg or a change of > 10 mmHg should alert the Emergency Physician that the patient may not be achieving adequate ventilation.** A loss of the ETCO_2 waveform implies that the patient is apneic or technical malfunctions are present. **Ensure that the patient is still breathing before looking for an equipment malfunction.** ETCO_2 is not perfect in predicting hypoxemia.^{25,26}

It is important to note the capnogram waveform and any changes from normal (Figures 159-1 through 159-4).³³ Changes can provide information about the patient's respiratory state. Expiration is composed of phases I, II, and III (Figure 159-1). Phase I is the baseline inspired gas. This is low in the patient breathing room air or using supplemental oxygen. This is absent of CO_2 in the patient on the ventilator. Phase II is the expired air (i.e., expiratory upstroke) and slopes upward. This represents the transition from dead space to alveolar flow. The α angle is the transition from phase II to phase III. Phase III is a plateau, which is the PCO_2 at the alveoli and is the ETCO_2 . The β angle is the transition from phase III to inspiration. Phase 0 or IV is the downward deflection (i.e., inspiratory downstroke) of the wave and inspiration. It represents fresh air inflow. The ETCO_2 is approximately 5 mmHg lower than the PCO_2 due to the dead space (Figure 159-1). The volume capnogram shows the subdivisions of the tidal volume (Figure 159-1B).

There are changes during sedation when compared to presedation waveforms (Figure 159-2). The capnogram can show changes in bronchospasm, cuff leaks, ETCO_2 , obstruction, and respiratory rate (Figures 159-2 through 159-4). Increased ETCO_2 can be due to increased CO_2 production (e.g., bicarbonate administration, fever, pain, shivering, or tourniquet release), increased

FIGURE 159-2. The capnogram with sedation. **A.** Presedation. **B.** During sedation the height is decreased. **C.** The respiratory rate presedation. **D.** During sedation the respiratory rate is decreased. (Used with permission from reference 119.)

FIGURE 159-3. Examples of capnograms. **A.** Hypoventilation. **B.** Return of spontaneous circulation after cardiac arrest results in tachycardia and CO₂ elevation from the now perfused tissues. (Used with permission from reference 33.)

pulmonary perfusion (e.g., increased blood pressure or cardiac output), decreased alveolar ventilation (e.g., chronic obstructive pulmonary disease [COPD], hypoventilation, partial airway obstruction, right mainstem intubation, rebreathing, or respiratory insufficiency), or malfunctioning equipment (e.g., exhausted CO₂ absorber, inadequate gas flow of fresh air, machine malfunction, or tubing leaks). Decreased ETCO₂ can be due to decreased CO₂ production (e.g., hypothermia), decreased pulmonary perfusion (e.g., cardiac arrest, decreased cardiac output, hypotension, or pulmonary embolism), increased alveolar ventilation (e.g., apnea, extubation, hyperventilation, metabolic acidosis, or total airway obstruction), or malfunctioning equipment (e.g., disconnections, leaks, or machine malfunction).

The changes associated with airway obstruction or bronchospasm are prolongation of phase II, an increased α angle, or a steeper phase III. Increased α angles $> 90^\circ$ are seen with ventilation/perfusion (V/Q) mismatches. Increased β angles suggest rebreathing.

AGENT SELECTION

A patient may present with numerous conditions that may require analgesia, sedation, or a combination of both. The first step is to determine exactly what is needed. Levels of sedation range from light or minimal depression of mental status to deep or heavy sedation where protective airway reflexes or hemodynamic stability may be compromised. **The goal of PSA is to achieve the desired endpoint with minimal risk of cardiorespiratory compromise.**¹¹

FIGURE 159-4. Examples of capnograms. **A.** Cuff leak. An unexpected drop during exhalation indicates that CO₂ is not reaching the detector. **B.** Airway obstruction or bronchospasm. The obstruction pattern is formed during exhalation, creating a gradual rise. (Used with permission from reference 33.)

Light sedation is aimed at blunting the patient's level of awareness to environmental stimuli and painful perceptions. Anxiety is alleviated and the patient maintains their responsiveness to verbal and physical stimuli. Protective airway reflexes are maintained. Deep sedation produces profound depression of awareness with the inability to respond to verbal stimuli. Careful monitoring of the cardiorespiratory status is essential in this setting as protective airway reflexes may be lost.

Certain agents, themselves or in combination, produce varied results in different patient subgroups. **Each patient requires individual consideration. Selecting the appropriate agent requires knowledge of the agent's potency, duration to onset, duration of drug effect, titratability, interaction with other drugs, and adverse effects profile.** Increasing dosages of an agent reduces its drug-specific effect in exchange for a nonspecific sedative effect complete with cardiorespiratory compromise. **The most common mistake in sedation is choosing the wrong agent for the specific goal.** For example, sedating a patient does not relieve pain. Sedation must be accompanied by analgesia if a patient is undergoing a painful procedure. This agent should ideally be titratable. **The only reliable and precise means of this is via intravenous administration.** Deep sedation should be provided only via the intravenous route. **Intravenous access is required if the patient undergoes deep sedation in case cardiorespiratory support is required or reversal agents must be administered.** Anxiolysis or mild sedation does not necessarily require intravenous access. Patients may be assessed on an individual basis as to whether intravenous access is deemed appropriate.

Synergistic effects must be considered when choosing a dosing schedule. For example, combining a benzodiazepine with a narcotic analgesic increases the potential effect of either agent alone.²⁰ It may become very difficult to titrate a sedative and an analgesic concurrently. Some practitioners advocate the use of a sedative initially followed by the addition of a narcotic analgesic as the patient's sedation is resolving. This works well for procedures that are extremely short and where muscle relaxation is key (e.g., simple reductions). The anterograde amnesia provided by most sedative agents is usually adequate to prevent the recollection of pain during the procedure. **The Emergency Physician should reduce the initial doses of multiple agents owing to the additive sedative effects. Small and incremental dosing enables a controlled titration to effect. Physicians must have a fundamental knowledge of the pharmacologic profiles of these agents. Allow the medications to reach peak effect before administering additional medication. Emergency Physicians are best served with a thorough knowledge of a few drugs as opposed to little knowledge over the entire procedural sedation agent spectrum.**

It would behoove an Emergency Physician to develop and practice four PSA drug regimens: sedative plus analgesic, pure sedation, dissociative analgesia and sedation (i.e., ketamine), and inhalation anesthesia (i.e., nitrous oxide). **Become well versed in the applications of these regimens and do not stray from the routine unless circumstances dictate a different regimen.** Identify one's limitations and obtain peer or Anesthesiology backup prior to procedural initiation. Provide adequate analgesia first when performing a painful procedure. Some degree of sedation will have already been established. Provide sedation with a pure sedative to obtain the endpoint of relaxation and sedation required to complete the procedure.

DRUG PROFILES

Table 159-4 provides a summary review of the agents routinely employed during PSA. **It is critical that the Emergency Physician is well versed on the individual agent and its effect in combination**

TABLE 159-4 The Agents Currently Available for PSA

Agent	Route	Pediatric dosing		Adult dosing		Onset (min)	Duration (min)	Adverse reactions	Contraindications
		Initial	Maximum	Initial	Maximum				
Benzodiazepines									
Midazolam (Versed)	IV	0.05 mg/kg	0.15 mg/kg	0.025 mg/kg	0.1 mg/kg	2–3	30–60	Respiratory depression	Hypersensitivity
	IM	0.05 mg/kg	0.20 mg/kg	0.05 mg/kg	0.15 mg/kg	10–20	60–120	Hallucinations	Renal impairment

Flumazenil (Romazicon)	IV	0.02 mg/kg (max 1 mg) (repeat every 1 min to effect)	0.2 mg every 15–45 sec	1 mg/15 min 3 mg/30 min	1–2	20–40	Nausea, vomiting
	IM	Same as IV			5–10	60–90	Concomitant tricyclic antidepressant ingestion Hypersensitivity In patient with chronic benzodiazepine use — may precipitate seizure

ICP, intracranial pressure; IM, intramuscular; IV, intravenous; PO, oral; PR, per rectum; SL, sublingual; SQ, subcutaneous.

with other medications. Medication routes, dosing parameters, side effects, contraindications, and anticipated complication management must be well known in advance.

The ideal agent is a single drug that has amnestic, anxiolytic, analgesic, and sedative properties. It should have a predictable and rapid onset of action. It should have a predictable and short duration of action with a rapid recovery. The ideal agent should be inexpensive, easy to administer, and have a wide safety margin to make loss of consciousness extremely unlikely. It should have little or no side effects, especially cardiovascular and respiratory. It must be easily reversible if necessary. There should be no residual effects at the end of the procedure. It is obvious that no agent meets all these criteria. We hope to minimize side effects, maximize benefit, allow quick recovery and dispositions, and produce reliable effects using small doses of multiple agents.

BENZODIAZEPINES

Benzodiazepines produce anterograde amnesia, anxiolysis, muscle relaxation, and sedation. They have no analgesic activity and must be used in conjunction with other agents for painful procedures. The use of a benzodiazepine allows less analgesic agent to be administered and may reduce the severity of adverse reactions. The major adverse effects of benzodiazepines are respiratory depression and hypotension. Benzodiazepine-associated respiratory depression is usually transient but can be reversed with flumazenil. Prevent hypotension by ensuring that the patient is euvolemic, using the minimal amount of a narcotic to produce analgesia, and carefully titrating the benzodiazepine.

MIDAZOLAM (VERSED)

Midazolam is an ultra-short-acting benzodiazepine that is metabolized by the liver and excreted by the kidney. Intravenous midazolam in dose ranges from 0.02 to 0.10 mg/kg will produce sedation within 2 to 3 minutes, redistribute rapidly, and provide a 20 to 30 minute duration of action. Most adults have adequate sedation and anxiolysis by a total dose of 5 to 7 mg, administered in 0.05 mg/kg or 1 to 2 mg increments every 3 to 5 minutes. **It is important to note the 2 minute delay in the peak central nervous system (CNS) effect. Allow midazolam time to work before additional dosing.** It may be used intranasally in children at a dose of 0.3 to 0.5 mg/kg as an effective means of sedation.³⁴ It is water-soluble and does not cause vascular irritation on injection as found in its relative diazepam. Midazolam is 3 to 4 times more potent than diazepam. It has anxiolytic and anticonvulsive properties. It is a potent amnestic agent with the added advantage of providing antegrade and retrograde amnesia. Midazolam alters the response to pain but does not reduce pain perception like all benzodiazepines. The addition of an analgesic agent is required when midazolam is administered for a painful procedure.

Midazolam is a potent respiratory depressant like all sedative agents. Midazolam can cause apnea by depressing the sensitivity of the hypothalamus to hypercapnia. It shifts the CO₂ response curve to the right and depresses its slope. **Its respiratory depressant effects are augmented in patients receiving opioids, with underlying lung disease (e.g., COPD), and with concomitant circulating CNS depressants (e.g., alcohol, barbiturates, and opioids).** Patients may become hypoxic even with normal respiratory rates.

Pulse oximetry is warranted when administering midazolam. Deaths related to the use of midazolam for sedation during endoscopy prompted the U.S. Food and Drug Administration (FDA) to recommend increased monitoring and caution with elderly or debilitated patients. There is a propensity for apnea when even very

small doses of midazolam are given in conjunction with fentanyl.³⁵ Midazolam may cause hypotension that is related to the dose and to the rate of administration. This effect is more likely to occur in hypovolemic patients or elderly patients. Paradoxical reactions (i.e., agitation, delirium, and excitation) can be produced from using midazolam and reversed with flumazenil.³⁶⁻³⁸

DIAZEPAM (VALIUM) AND LORAZEPAM (ATIVAN)

Diazepam and lorazepam have longer half-lives than midazolam. Either agent may be used for PSA. They are more difficult to titrate and have a longer duration of action. Neither of these characteristics is well suited to PSA. **Midazolam has greater earlier sedation, less recall, less pain upon injection, higher 90 minute alertness scores, and more patients ready for discharge at 90 minutes post-procedure than diazepam.** Diazepam results in more respiratory depression, hypotension, and phlebitis than midazolam. **Diazepam and lorazepam have no advantage over midazolam if the goal is to produce a short and titratable state of anxiolysis and sedation.** These agents are not often used for PSA.

OPIOIDS

Opiates provide analgesia with minimal sedation and no anxiolysis. They have a long track record showing a predictable performance. The respiratory and central nervous system depression can be readily reversed with naloxone and nalmefene. Opiates are relatively inexpensive and used in a balanced approach to PSA. Agents in this class include morphine, fentanyl, meperidine, sufentanil, and alfentanil.

Morphine has been the mainstay narcotic analgesic. The use of potent synthetic short-acting opioids for analgesia and sedation has been common practice for PSA. These drugs are particularly appealing for their short half-lives, rapid onset of action, limited cardiovascular side effects, ease of controlled administration, and the availability of a rapidly acting reversal agent. The use of these agents requires a thorough familiarity with their pharmacologic properties and side effects. A PSA repertoire should include one of the potent synthetic narcotics. It is better to master one drug than dabble in the pharmacology and administration of three different drugs with different dosing regimens.

MORPHINE

Morphine is a “good old” potent analgesic with a lot of clinical experience. It is the prototype opioid to which all others are compared. Incremental intravenous dosing of 0.05 to 0.20 mg/kg every 3 to 5 minutes provides a nice range over which to carefully titrate to an individual analgesia requirement. It begins working in 1 to 3 minutes and peaks within 15 to 20 minutes. Morphine has a duration of activity of 3 to 4 hours. It provides often-needed pain relief after the procedure has been completed. It is metabolized by the liver and excreted by the kidney. Morphine, as with all opioids, decreases the medullary response thereby promoting hypercapnia and hypoxia. Histamine release with hypotension, nausea, vomiting, itching, bronchospasm, and loss of vascular tone are common side effects of morphine administration. Morphine has steadily lost ground to the designer opioids with better cardiovascular stability (e.g., fentanyl, sufentanil, and alfentanil).

FENTANYL (SUBLIMAZE)

Fentanyl is highly lipid soluble and 75 to 125 times more potent than morphine. Peak analgesia is achieved in 2 to 3 minutes after intravenous administration. The terminal half-life is 130 to 220 minutes.

The clinical effectiveness is limited to approximately 30 minutes due to rapid tissue redistribution. Fentanyl is a “20 minute drug for a 20 minute procedure.” It is metabolized in the liver with renal and hepatic excretion. Approximately 20% is excreted as the unmetabolized parent compound. The major side effect of fentanyl is respiratory depression. **Hypotension is less common than with morphine because fentanyl does not induce histamine release.**

Administer fentanyl very slowly and in small increments. Patients may experience rigidity of their chest muscles (i.e., the “rigid chest syndrome”) when it is administered intravenously too rapidly.³⁹ This syndrome can severely impact ventilation to the point that the patient must be paralyzed to facilitate adequate ventilation. Administer incremental doses of 0.5 to 1.0 µg/kg or 10 to 100 µg boluses slowly intravenously until adequate analgesia is achieved.

Fentanyl may be administered intranasally at a dose of 0.7 to 1.5 µg/kg.⁴⁰ Concentrated fentanyl at a dose of 1.7 µg/kg is equivalent to 0.1 mg/kg of morphine.⁴¹ Its advantages include simple rapid administration, limited training required to administer it intranasally, and faster analgesia when compared to establishing intravenous access and administering an intravenous opioid.⁴⁰ The disadvantages include having to restrain the child’s head for the administration and the time it takes to administer the medication. Atomizer devices can minimize or eliminate these issues.

An alternative method is to administer fentanyl through a nebulizer mask.^{42,43} Nebulized fentanyl at a dose of 3 µg/kg through a breath-actuated mask is effective.⁴² This study only used children over the age of 3 years because younger children have difficulty triggering the mask. Another study used a standardized nebulizer system to deliver 4 µg/kg of fentanyl, a dose equivalent to 0.1 mg/kg of morphine, to children between 4 and 13 years of age.⁴³ Appropriate analgesia was achieved with this dose and administration system.

Fentanyl is contraindicated in children less than 6 months of age. It stimulates the central vagus nucleus in the brainstem. This can result in a prolongation of the refractory period of the atrioventricular (AV) node and significant bradycardia.

The rigid chest syndrome may occur to the point at which the patient may not be ventilating and attempts at assisted ventilation with a bag-valve-mask device are unsuccessful.³⁹ The patient may then become hypoxic, bradycardic, and eventually die. This phenomenon has been well documented in children. The rigid chest syndrome is the reason many are reluctant to administer fentanyl. **It occurs during rapid intravenous administration, so give it slowly.** It only occurs at high doses (e.g., > 15 µg/kg) to anesthetic doses (e.g., 50 to 100 µg/kg). **The doses used for PSA are safe and usually do not result in the rigid chest syndrome.** Immediately administer naloxone intravenously if the rigid chest syndrome develops. The use of naloxone does not often work to overcome the rigid chest syndrome.³⁹ The patient may require paralysis and orotracheal intubation to overcome the rigid chest syndrome.³⁹

SUFENTANIL (SUFENTA)

Sufentanil is an extremely potent narcotic analgesic. It is 5 to 10 times more potent than fentanyl and 500 to 1000 times more potent than morphine. It is metabolized and eliminated more rapidly than fentanyl. There is no significant advantage to using sufentanil over fentanyl for most PSA applications.

The one advantage is that its potency and small-volume dosing enable it to be delivered intranasally in the pediatric population. The American College of Emergency Physicians’s Guideline to Pediatric Sedation is a proponent of this application.⁴⁴ Sufentanil has an onset of action in 5 to 15 minutes and a duration of action lasting 1 to 2 hours when administered intranasally. It provides exceptional cardiovascular stability but maintains the profound respiratory

depressive effects inherent in the opioid class of agents. Careful patient selection is well advised when considering sufentanil.

ALFENTANIL (ALFENTA)

Alfentanil is less lipid soluble than fentanyl and less likely to accumulate if multiple doses are required. It is 10 to 20 times more potent than morphine. It is one-tenth to one-fifth as potent as fentanyl. The duration of analgesia is ultrashort. Its onset of action is within seconds and lasts only 2 minutes. **Alfentanil is too short-acting to use for PSA.** Total dosing is 8 to 10 µg/kg delivered in small repeated dosing aliquots. Its half-life is only 80 minutes. The adverse effect profile is like fentanyl except it may cause more respiratory depression.⁴⁵ The rigid chest syndrome may be seen with alfentanil. Alfentanil is more appropriate to use for the induction of general anesthesia.

REMIFENTANIL

Remifentanil is a synthetic short-acting opioid. It is commonly used by Anesthesiologists for analgesia that is deep and rapid. It causes little central nervous system depression. One advantage is that it is metabolized by blood esterases and does not rely on the kidney or liver. The half-life is 3 to 8 minutes, often too short for the Emergency Department unless redosed. There has been little use in the Emergency Department.^{46,47}

MEPERIDINE (DEMEROL)

Meperidine is one-tenth as potent as morphine. It was the most commonly administered opioid agent for pain in the United States. It is less often used due to its euphoric effects. It is not used for PSA because it is hard to titrate and takes a long time to reach peak activity.

DISSOCIATIVE AGENTS

KETAMINE (KETALAR)

Ketamine is a unique pharmaceutical agent that provides amnesia, analgesia, anxiolysis, and sedation.^{48,49} Its safe and effective use in pediatric sedation and analgesia is well studied.⁵⁰ It is the most commonly used anesthetic agent throughout the world. It has the best safety profile in terms of cardiorespiratory complications of any agent. Ketamine is a derivative of phencyclidine (PCP) that generates a functional and electrophysical dissociation between the brain’s cortical and limbic systems. This results in a dissociative state whereby the patient is in a trance-like cataleptic condition in which sensory perceptions and memory are blunted. The patient appears awake yet is dissociated from their environment. Random tonic movements will occur and gentle physical restraint may be required.

Ketamine is a positive inotrope. It increases the heart rate, blood pressure, cardiac output, and intracranial pressure.⁵¹ The blood pressure and heart rate may slightly increase with the use of ketamine. The systolic and diastolic blood pressure may increase up to 30 mmHg with an average of 15 mmHg. The heart rate may increase up to 30 beats per minute with an average of 15 beats per minute. These effects are believed to be due to decreased uptake of catecholamines at neural endplates.

Ketamine’s effect on the respiratory system includes bronchodilation, a slight increased respiratory rate, increased secretions, and potential laryngospasm. Ketamine is a potent bronchodilator. **Ketamine does not depress airway reflexes like narcotics or benzodiazepines.** The side effects of increased respiratory secretions can be blocked with atropine or glycopyrrrolate.^{52,53} Administer atropine

prior to or concurrently with ketamine in a dose of 0.01 mg/kg to a maximum of 0.3 to 0.5 mg. Administer glycopyrrolate before ketamine in a dose of 0.005 mg/kg to a maximum of 0.25 mg. Atropine administration is associated with less adverse respiratory events, less recovery agitation, and less vomiting during recovery than glycopyrrolate.⁵⁴ Atropine causes more side effects compared to glycopyrrolate because it crosses the blood-brain barrier.^{55,56} A recent trend is to not use an antisialogogue because excessive respiratory secretions are uncommon and not associated with adverse respiratory events.⁵⁷

Ketamine may be administered by several routes. Rapid predictable effects are best seen with parenteral administration.⁵⁸ Intravenous dosing is 0.5 to 1.0 mg/kg increased slowly up to 2 mg/kg.⁵⁹ This is approximately one-fourth of the intramuscular dosing of 1 to 6 mg/kg, usually 2 to 4 mg/kg. A dissociative state is produced in less than a minute with intravenous administration and 2 to 10 minutes via the intramuscular route. Intravenous dosing may be repeated at 5 minutes with an additional 1 to 2 mg/kg. Intramuscular dosing may be repeated at 10 minutes with an additional 2 to 4 mg/kg if adequate sedation has not been achieved. Ketamine may be given orally at 5 to 6 mg/kg or rectally at 5 to 10 mg/kg. Its titratability is poor orally and rectally. This makes its effectiveness much less predictable. Intravascular dosing lasts 20 to 25 minutes with a single administration.⁶⁰ Intramuscular dosing may be more commonly associated with laryngospasm when compared to intravenous administration.⁶¹

Ketamine may be administered intravenously or intramuscularly due to its safety profile.⁶² Intramuscular administration is preferable when intravenous access is difficult to establish, intravenous access is not required for another reason, and for procedures lasting 15 to 25 minutes due to its longer effects. Intravenous administration is preferable if intravenous access is required for another reason, if intravenous access is easily obtained, for procedures lasting less than 10 minutes, and to decrease recovery time.⁶³

The lack of cardiorespiratory compromise of ketamine and the effectiveness of intramuscular administration make it an excellent agent for pediatric PSA. Patients tend to remain hemodynamically stable when using ketamine. This reduces the need for intravenous fluid boluses and reversal agents. This is especially true in children in whom intravenous access can be a difficult procedure. A medication that can be safely administered intramuscularly not only simplifies PSA but also improves patient and family satisfaction.

Contraindications to the use of ketamine include age less than 3 months, procedures involving pharyngeal stimulation, known cardiovascular disease, concurrent head trauma with altered mental status, airway compromise including previous tracheal surgery or stenosis, glaucoma, known central nervous system mass lesions, active upper or lower respiratory disease, and porphyria. Ketamine can rarely cause acute pulmonary edema.^{64,65} Evidence now shows it does not increase intraocular pressure or intracranial pressure significantly.⁶⁶⁻⁶⁹ Allergic reactions to ketamine are rare.⁷⁰ It can cause cardiac arrhythmias.⁷¹ Information suggests ketamine is safe to administer in head injury patients in the pediatric intensive care unit.⁷²

Patients will exhibit a slow emergence from the effects of ketamine over the course of 1 to 2 hours. Ketamine is metabolized and excreted by hepatic mechanisms. Place the patient in a quiet room that is free of excessive external stimuli to minimize the possibility of them becoming hyperactive or overstimulated by their surroundings. Ketamine-associated emesis is a commonly seen side effect.^{61,73-75} The rate of emesis is higher with intramuscular administration, with initial intravenous doses over 2.5 mg/kg, and with total doses ≥ 5.0 mg/kg.^{61,73} However, a study of over 1000 children refuted the theory that emesis is dose related.⁷⁴ The use

of intravenous ondansetron at 0.15 mg/kg to a maximum 4 mg decreased the rate of ketamine-associated emesis.⁷⁵

Emergence reactions are hallucinations that occur as the ketamine wears off and the patient awakens. They may be seen in up to 50% of adults and up to 10% of children given ketamine. The etiology of these emergence reactions is unknown. There is an association of emergence reactions with an age over 10 years, female sex, rapid intravenous administration, stimulation during the recovery period, and personality disorders. Rarely will a child less than 10 years of age develop an emergence reaction with hallucinations.

The incidence of emergence reactions can be decreased. Administer the ketamine slowly intravenously. Place the patient in a dark, quiet room with minimal sensory stimulation during the recovery period. Treatment with benzodiazepines is indicated if an emergence reaction develops. The concurrent administration of midazolam in a dose of 0.025 to 0.050 mg/kg can reduce emergence reactions. There is no advantage of combining midazolam with ketamine in preventing an emergence reaction.⁷⁶ Midazolam can significantly reduce emergence reactions in adults.⁷⁷ A review noted no benefit and no harm in coadministering benzodiazepines.⁷³ The concurrent use of midazolam is Physician-dependent, has no serious sequelae, and may reduce emergence reactions.

KETAMINE-PROPOFOL COMBINATION (KETOFOL)

The use of ketamine and propofol in combination has been coined "ketofol." The reason these agents were combined was to provide appropriate sedation and analgesia while decreasing adverse events by using less of each individual agent. Ketamine potentiates the sedation of propofol without cardiac or respiratory depression. The combination of ketamine and propofol is effective for PSA, although the evidence does not show a clear benefit over ketamine alone.^{21,78-86} The combination has similar complication rates, similar adverse effects, and similar satisfaction scores when compared to using ketamine as a single agent.^{21,86}

There is no established standard dosing. Prepare both the ketamine and the propofol as a 10 mg/mL solution. These agents can then be administered intravenously in a 1:1 ratio in aliquots of 1 to 3 mL every 2 minutes until the desired effect is achieved. Another option is to mix equal parts of both solutions into one syringe and administer the appropriate volume to deliver 0.5 mg/kg of each agent. Additional boluses can be administered to deliver 0.25 mg/kg of each agent every 2 to 3 minutes until the desired effect is achieved.

SEDATIVE-HYPNOTICS

The sedative-hypnotics are a diverse category of agents that include thiopental, methohexital, etomidate, and propofol. **Sedative-hypnotics provide anxiolysis and sedation with various degrees of amnesia. They provide no analgesia.**

BARBITURATES

Short-acting barbiturates (i.e., thiopental, pentobarbital, and methohexital) are effective PSA agents. They provide good titratability with a rapid onset of action. Barbiturates provide amnesia, hypnosis, and sedation. They are highly lipophilic and cross the blood-brain barrier readily resulting in an onset of action in less than 1 minute. They have short half-lives that promote a rapid recovery and minimize the risks inherent in prolonged sedation. **Their major drawbacks are respiratory depression, apnea, transient hypotension, and lack of a reversing agent. The window between PSA, deep sedation, and general anesthesia is extremely narrow.** These agents are rarely used for PSA in the Emergency Department.

THIOPENTAL (PENTOTHAL)

Thiopental is one of the more commonly used barbiturates. It has an extremely rapid onset of action of 10 to 20 seconds with a peak activity in 1 minute. Its sedative effect lasts 3 to 10 minutes. Thiopental is titratable in doses of 0.5 to 1.0 mg/kg intravenously. Rarely is more than 2 mg/kg required.

It may be administered rectally at 20 to 25 mg/kg in children who require sedation without intravenous access. Sedation is achieved within 5 to 8 minutes. Rectal administration does not result in apnea or respiratory depression. Thiopental is often administered rectally for laceration repairs in children.

METHOHEXITAL (BREVITAL)

Methohexital has a profile like thiopental with a few noted exceptions. It is twice as potent as thiopental. It has much less of an effect on decreasing myocardial contractility and decreasing vascular tone. A single study has convinced most people not to use this drug in the Emergency Department.⁸⁷ One hundred and two patients were given methohexital with a mean cumulative dose of 1.6 mg/kg. Three patients developed hypotension. Twenty-two patients developed respiratory depression requiring bag-valve-mask assistance. Five of the 22 patients with respiratory depression developed transient apnea.

Methohexital may be administered as repeated incremental bolus dosing or via a titratable continuous infusion. Begin with a 0.5 to 1.0 mg/kg bolus followed by an infusion at 50 µg/kg/min. Titrate infusion rates upward to effect with a maximum rate of 75 µg/kg/min. Bolus dosing is best delivered as 0.5 to 1.0 mg/kg to a maximum of 20 mg every 45 to 60 seconds until the desired endpoint is attained. Maximum sedation is achieved at 40 seconds.

Respiratory depression is common and independent of the dose or concomitant administration of a narcotic or benzodiazepine. Patients may require assisted ventilation with a bag-valve-mask device or ventilator assistance until the effect of the drug clears. **Respiratory depression is minimized by first administering the analgesic agent to control pain followed by methohexital for sedation to effect.** Do not use methohexital in children younger than 12 years of age.

PENTOBARBITAL (NEMBUTAL)

Pentobarbital is a short-acting barbiturate that is effective for pediatric sedation during nonpainful diagnostic procedures (e.g., computed tomography or magnetic resonance imaging). **Controlled sedation levels are best achieved with titrated small incremental intravenous dosing.** It may also be administered intramuscularly, orally, and rectally. Intravenous administration will induce sleepiness within 30 seconds with a duration of action up to 15 minutes. Other dosing methods take longer to work with a duration of action ranging from 1 to 4 hours.

Pentobarbital is primarily administered intravenously or rectally. Initial intravenous dosing at 2.5 mg/kg may be sufficient. Subsequent doses of 1.25 mg/kg every 30 seconds to effect will minimize over-sedation and limit hypoxia. Other side effects are nausea, vomiting, and paradoxical hyperactivity. A maximum total dose of 6 mg/kg or 100 mg should mark the dosing endpoint. Older children may exceed this limit with due caution. Rectal dosing is age-dependent. Administer 3 to 6 mg/kg to a maximum of 100 mg in children younger than 4 years of age and 1.5 to 3 mg/kg to a maximum of 100 mg in children older than 4 years of age.

ETOMIDATE (AMIDATE)

Etomidate is an imidazole derivative that is commonly used for the induction of anesthesia or rapid sequence induction. It produces

amnesia, anxiolysis, and sedation equal to that of barbiturates but with fewer hemodynamic affects.⁸⁸ It is ultra-short-acting and in a class of its own. It may produce unconscious sedation like the barbiturates. There is a narrow window for the use of etomidate in PSA. It can be used for an emergent procedure in a patient with borderline low blood pressure and ketamine is contraindicated. It is often used when there may be contraindications to other sedating agents due to hypotension and or other injuries.

There is evidence showing that intensive care unit patients given etomidate are at greater risk for the development of adrenal insufficiency.⁸⁹ Etomidate inhibits 11-beta-hydroxylase causing a decrease in serum cortisol levels. This was initially found in patients who were receiving continuous intravenous administration of etomidate. There is evidence that adrenal insufficiency may occur even after a single dose of etomidate.⁹⁰ These studies were conducted on patients receiving etomidate for induction prior to intubation. The study populations had higher injury severity scores and were receiving higher doses of etomidate when compared to PSA doses. This effect on the adrenal gland is usually transient and resolves after 24 hours. The actual effect on morbidity and mortality is still not clear.^{91,92} Adrenal suppression in the Emergency Department patient undergoing PSA for a short procedure and then being discharged is probably of little to no consequence.

Etomidate is one of the more frequently used agents for sedation and PSA. It has a shorter onset and faster recovery time than midazolam.^{93,94} Myoclonus is a well-described adverse effect that is unique to etomidate.⁹⁵⁻⁹⁷ Myoclonus can be severe enough to result in a decreased oxygen saturation and full-body rigidity requiring a brief period of respiratory support. A rare adverse event is agitation or an "emergence-type reaction" as the effects of etomidate wear off.⁹⁸ These few adverse effects do not outweigh its benefit of a minimal effect on the cardiovascular system.

PROPOFOL (DIPRIVAN)

Propofol is a highly lipid-soluble compound with ultra-short sedative hypnotic properties. **It can produce amnesia, anxiolysis, hypnosis, and profound sedation.**^{48,99,100} **Propofol has no analgesic properties.** It is unrelated to the barbiturate or benzodiazepine classes. The onset of action is extremely rapid and within 15 to 30 seconds. The maximal effect is seen within 30 to 45 seconds. The duration of effect is typically only 8 to 15 minutes, even after prolonged administration. Propofol is contraindicated if the patient has a known sensitivity or allergy to egg or soy products.

Dosing can be delivered intravenously via repeated small 20 mg doses at 2 minute intervals or initial loading of 0.5 to 2.0 mg/kg followed by infusion rates of 25 to 130 µg/kg/min. A simple method of titrating propofol for short procedures is to administer 1 mg/kg initially with repeat boluses of 0.5 mg/kg every 1 to 2 minutes as needed to achieve or maintain adequate sedation. Effective total doses may range from 20 to 150 mg. A continuous infusion of 50 to 70 µg/kg/min can be used to produce a sleep-like state with minimal respiratory depression. Continuous infusions allow the patient to be easily aroused by verbal stimuli and recover within 2 to 3 minutes of stopping the infusion. Induction dosing or rapid bolus injection can result in profound respiratory depression and hypotension, especially in the hypovolemic patient. High-dose oxygen can decrease the hypoxemia.¹⁰¹ It can be associated with bronchospasm, laryngospasm, and pulmonary edema in rare cases.¹⁰² Propofol can be coadministered with fentanyl or ketamine (i.e., ketofol) for painful procedures requiring a combination of sedation and analgesia. Propofol can turn the urine green.¹⁰³

The high lipid content of the propofol solution causes pain upon injection. The administration of intravenous lidocaine immediately prior to the propofol may decrease the injection pain. Inject

0.5 mg/kg up to a maximum of 40 mg of lidocaine.¹⁰⁴⁻¹⁰⁶ Be cautious to not exceed the maximum toxic dose of 4.5 mg/kg in small children. An alternative is to add 30 mg of ephedrine to 20 mL of 1% propofol solution to decrease the injection pain.¹⁰⁷ An additional advantage of ephedrine is that it counteracts the potential propofol-associated hypotension.

FOSPROPOFOL

Fospropofol is a water-soluble prodrug of propofol.^{108,109} This formulation is not associated with many of the lipid emulsion effects. This formulation results in decreased injection pain, has a wider therapeutic window, and allows long-term sedation without a large lipid load. Fospropofol is currently FDA approved for monitored anesthesia care. Future studies and safety data are required before this agent can be recommended for PSA.

DEXMEDETOMIDINE

Dexmedetomidine is an alpha-2 agonist with analgesic, anxiolytic, and sedative properties that works as well as midazolam.^{110,111} It decreases central adrenergic tone by blocking norepinephrine release from presynaptic and postsynaptic central nervous system receptors. Dexmedetomidine causes a minimal respiratory depression. It has a delayed onset of action in 15 to 30 minutes and its effects persist up to 3 hours after the infusion is discontinued. It is administered intravenously at 2 µg/kg over 10 minutes followed by a maintenance dose of 1 µg/kg/h. The side effects include bradycardia, cardiac arrhythmias, hypertension with loading, and hypotension with maintenance infusions. This agent is often used in the outpatient setting for elective computed tomography and magnetic resonance imaging scans.^{112,113} Its delayed onset, prolonged effects, and adverse effect profile make it an agent not recommended for PSA.

MISCELLANEOUS AGENTS

Several agents can be used for the sedation of children in the Emergency Department and outpatient setting. **These agents are not used for PSA.** These agents include chloral hydrate and DPT (meperidine [Demerol], promethazine [Phenergan], and chlorpromazine [Thorazine]). Chloral hydrate is not often used in the Emergency Department. **Never use the DPT cocktail in any setting.**

CHLORAL HYDRATE

Chloral hydrate is a time-tested, effective, and pure sedative-hypnotic. It has no analgesic properties. Its primary usage has been for sedation during nonpainful diagnostic testing. The oral dose is 20 to 100 mg/kg to a maximum of 2000 mg. Most children require 50 to 75 mg/kg to achieve proper sedation. It has an onset of action of 15 to 60 minutes and a duration of effect of 1 to 2 hours. Its effects may persist for up to 24 hours. Rectal dosing is not recommended due to erratic absorption. Contraindications include renal impairment, hepatic impairment, or hypersensitivity to the agent itself. The wide dosing range and variability of onset and duration make chloral hydrate a far-from-perfect sedative for use in the Emergency Department. Its primary usage has been with outpatient testing.

DPT

DPT, also known as the “lytic cocktail,” was popularized for the induction of general anesthesia. It was expanded to use in the outpatient setting and had many adverse events. It consists of Demerol, Phenergan, and Thorazine in a 2:1:1 or 4:1:1 mixture. It is administered intramuscularly at a dose of 1 mg/kg based upon the Demerol component.

Intramuscular absorption is erratic with up to one-third of children never obtaining moderate to adequate sedation. It produces too deep a level of sedation that is difficult to reverse in the other two-thirds of the children. The mean time to Emergency Department discharge is 5 hours due to the prolonged sedation. The mean time for the child's behavior to return to normal is 19 ± 15 hours.

Many children have suffered respiratory depression, hypoxemia, and apnea due to this agent. DPT is an agent of the past due to its prolonged action and significant potential for respiratory depression. The DPT agent has no use in the Emergency Department. Agents now exist that are safer, are easier to use, and have a more rapid recovery. Its use is described here only for completeness. Do not use this drug combination for PSA.

INHALATION AGENTS

NITROUS OXIDE

Nitrous oxide is an anesthetic gas that has been used in the outpatient procedural arena since the 1950s (Chapter 158). It produces amnesia, anxiolysis, and sedation with a variable degree of analgesia.¹¹⁴ It dissociates a patient from pain and their surroundings. Nitrous oxide is self-delivered via a handheld demand valve mask in a 50/50 mixture with oxygen and can be administered safely in concentrations of up to 70%.¹¹⁵ The risk of oversedation is minimized with this mode of administration. The patient will drop the mask once they are too sedated to coordinate self-administration.

The onset of action of nitrous oxide is 30 to 60 seconds with a peak in 3 to 5 minutes. It has a similar washout period once delivery is ceased. Nitrous oxide is eliminated unchanged via the lungs thereby minimizing any drug-drug interactions. Nausea and vomiting are common.¹¹⁶ The feelings of disorientation and agitation are common. Nitrous oxide can rarely produce laryngospasm.¹¹⁷

Contraindications to the use of nitrous oxide include impaired mental status, concomitant intoxication, pregnancy, potential to expand air-filled cavities (e.g., pneumothorax or bowel obstruction), and coadministration of narcotics within 4 hours as general anesthesia may be induced. Relative contraindications include a full meal within 1 hour of its use and children less than 5 years of age due to delivery system compliance.

REVERSAL AGENTS

It should be well recognized that a desired endpoint can be overshoot resulting in an apneic and hypotensive patient despite good preprocedural assessments, appropriate agent selection, appropriate dosing, and titration. There are two reversal agents (i.e., flumazenil and naloxone) that can be of help in these situations. **Reversal agents are not routinely required following PSA. They are reserved for the patient who develops apnea, hypoxia, and/or hypoventilation.**

FLUMAZENIL (ROMAZICON)

Flumazenil is a benzodiazepine antagonist that works by competitive inhibition at the gamma-aminobutyric acid (GABA) receptor. **Intravenous administration will rapidly reverse central nervous system depression and respiratory depression from benzodiazepines within 2 minutes.** Begin by administering a dose of 0.02 mg/kg to a maximum of 0.2 mg over 15 seconds. Administer additional 0.2 mg doses at 1 minute intervals until the desired state of consciousness is achieved. Maximum dosing is 1.0 mg over 15 minutes or 3.0 mg over 60 minutes. **The benzodiazepine metabolites are active longer than the reversal agent. Carefully monitor a patient receiving flumazenil for resedation.** A safe recommendation would require a minimum observation of 2 hours after the last dose is given.

Flumazenil is contraindicated in patients taking benzodiazepines for an extended amount of time or patients with an underlying seizure disorder. These patients are prone to seizure activity with the administration of flumazenil. It is also contraindicated in patients taking tricyclic antidepressants.

NALOXONE (NARCAN)

Naloxone is a pure opioid antagonist that works by competitively inhibiting narcotics at the opioid receptor. **Intravenous administration reverses the respiratory depressive effects of opioids within 1 to 2 minutes. Its clinical duration of effect is approximately 20 to 30 minutes.** Long-acting narcotics may cause resedation. **The opioids and their metabolites are active longer than the reversal agent. Carefully monitor a patient receiving naloxone for resedation and respiratory depression.** The drug can be delivered via multiple routes (i.e., endotracheally, intramuscularly, intravenously, subcutaneously, and sublingually). The administration of 1 to 2 mg intravenously in adults and 0.1 mg/kg in children will reverse most respiratory arrest situations. Administer additional doses every 2 to 3 minutes to a total of 10 mg. Actively seek another etiology of the sedation and respiratory depression, other than narcotics, if the respiratory depression is not reversed after 10 mg of naloxone. **Use caution as naloxone can result in opioid withdrawal in those with physical dependence or intoxicated with narcotics.**

Small aliquots of 40 µg titrated to effect may be delivered in a situation where the patient is slightly oversedated and rapid full reversal of the narcotic is not desired. Mix 0.4 mg of naloxone with 9 mL of normal saline to produce a concentration of 40 µg/mL. Administer 1 to 2 mL aliquots every 1 to 3 minutes to alleviate respiratory depression yet maintain the narcotic analgesic effect.

TECHNIQUE

The technique of PSA can be quite variable depending on the institution and the agents chosen to administer. A sample PSA protocol can be found in **Table 159-5. PSA requires two persons at a minimum.** One person must monitor the patient while the other administers the medication and performs the procedure. **Take the time to do it right!** The right time to perform PSA is not when the Emergency Department is at capacity and the acuity of other

patients is high. The medications must be titrated to effect which can take up to 15 minutes.

ASSESSMENT

Nursing personnel managing the care of the patient receiving PSA must continuously monitor the patient's airway, breathing, circulation, and mental status. It is imperative to observe the rise and fall of the chest wall with the focus upon the work of breathing. **Relying solely on pulse oximetry may give a false sense of security. Observation of a progressive slowing in the patient's respiratory effort is a sign of impending hypercapnia or hypoxia that is seen well ahead of any monitoring alerts or cutoffs.** Avoid sterile wraps that cover the entire face or chest. Observe the patient for a decrease in respiratory rate or depth of breathing. Notice any abnormal airway sounds indicative of partial airway obstruction, bronchospasm, laryngospasm, or stridor. Visually monitor the peripheral perfusion of assessments of skin and mucosa color, moisture, and temperature. Assess pulse quality and rate in addition to frequent blood pressure determinations. Blood pressure monitoring may awaken the patient and forgo the ability to complete the diagnostic or therapeutic interventions in cases of mild sedation (e.g., pediatric sedation for neuroimaging). Continually assess the patient's level of consciousness throughout the procedure and recovery period. The previously mentioned scoring systems offer one means of determining the level of sedation. Record the patient's responses to verbal stimuli, if applicable.

AFTERCARE

The patient must meet several criteria to ensure their safety before leaving the Emergency Department. Vital signs must be appropriate to the age of the patient and comparable to preprocedural parameters. The respiratory effort must return to baseline. Mobility must be equal to or better than that before the procedure. The patient must be able to follow commands and discharge instructions. Preprocedural levels of consciousness and mental status must be present. The patient must be able to tolerate oral fluids. The pain of the procedure for which PSA was performed must be controlled. The patient must be discharged in the care of a responsible adult who understands the discharge instructions. All these criteria must be documented in the medical record and timed prior to discharge.

Patients who have received multiple medications or a reversal agent will require a longer recovery period. A 2 hour observation window is prudent. Provide written discharge instructions and explain them to the patient and the responsible adult who will accompany the patient home. Examples of preprinted pediatric and adult discharge sheets are presented in **Tables 159-6 and 159-7.**

COMPLICATIONS

Respiratory depression and hypoxia are inherent risks of PSA despite efforts to minimize risk with prudent patient risk-benefit assessment, appropriate drug selection, and appropriate dosing.³ Individual patient responses to analgesic, hypnotic, or sedative agents can be very unpredictable. Part of the preparation includes bedside availability of reversal agents in anticipation of these complications.

The first course of action is simply to provide patient stimulation in the event of respiratory depression. Painful stimulation is most easily applied by continued traction or manipulation of the injured extremity. Patients undergoing PSA will frequently not become apneic until after the procedure is complete and the noxious stimulus is no longer present. The jaw-thrust maneuver is another

TABLE 159-5 A Sample PSA Protocol

1. Place the patient supine in bed with the rails up.
2. Obtain intravenous access with a large-bore angiocatheter and hang a 1 L bag of normal saline.
3. Apply the cardiac monitor to record pulse, respiratory rate, and blood pressure at start of procedure and every 3–5 minutes during the procedure.
4. The nurse must monitor the patient's level of consciousness at the start of the procedure and every 3–5 minutes during the procedure.
5. Apply continuous pulse oximetry to monitor and maintain the oxygen saturation > 95%, or no less than 3–5% below baseline.
6. Apply supplemental oxygen by nasal cannula at 2–4 L/min.
7. Place the resuscitation cart at the bedside.
8. Set up suction equipment and ensure that it is working properly.
9. Have the required medicines at the bedside and drawn up into labeled syringes.
10. Have the reversal agents (naloxone and flumazenil) at the bedside, not drawn up unless needed.
11. Administer and titrate the medications to effect.
12. Administer local or regional anesthesia if indicated.
13. Perform the procedure for which PSA was performed.
14. Administer additional doses of sedatives and analgesics as needed.
15. Closely observe and monitor the patient until they are awake, alert, and back to baseline.

TABLE 159-6 Pediatric PSA Discharge Instructions

In order to best care for your child, they were given medications that can cause drowsiness and clumsiness over the next few hours. While most of the effect has worn off by this time, their coordination and judgment may still be affected. During this time it is very important to directly watch your child's activity to assure their safety.

Diet . . . Do not let them eat or drink for the next 2 hours. At that time, start with sips of water or juice before giving them solid foods. Children younger than 1 year may start feeding in 1 hour.

Activity . . . For the next 6–8 hours, do not allow them to participate in any activity where lack of coordination could cause injury. Examples would include biking, climbing, running, playing on swing sets or monkey bars, swimming, or even stair climbing without your assistance. Your direct observation of their activities is very important during this recovery time. You need to directly watch your child if they are bathing, showering, cooking, or using any tool or device where injury could result due to poor judgment or coordination.

Sleep . . . Your child may wish to nap or sleep for the duration of the night. You need to awaken them in 2 hours. If they should appear as they normally would after being awakened from sleep, you can let them finish their nap or sleep through the night.

Contact or return to the Emergency Department immediately if:

1. You notice anything you feel is unusual about your child.
2. You feel your child's breathing is abnormally fast, slow, or shallow.
3. Your child's skin appears pale or grayish in color.
4. You have more difficulty awakening your child.
5. Your child has repeated vomiting (3 or more times).

Emergency Department phone number: _____

method of providing significant stimulation while placing yourself at the patient's head and assisting ventilation by opening the airway. Support the patient's ventilation with a bag-valve-mask device while the appropriate reversal agent(s) are being drawn up if stimulation is inadequate. Naloxone will rapidly reverse the respiratory depression if a narcotic was administered. Flumazenil will reverse the respiratory depression if a benzodiazepine was administered.

There is no way to determine which reversal agent is best suited to reverse the respiratory depression when both a narcotic and benzodiazepine have been administered. A rational approach is to first administer flumazenil. This maintains the needed analgesia while, hopefully, improving the respiratory drive. Administer naloxone if the flumazenil does not reverse the respiratory depression.

Laryngospasm is a real but relatively rare event during PSA provided the appropriate patient and drug selection was employed.³ Fentanyl, ketamine, midazolam, and phenobarbital may all cause laryngospasm. This tends to be a brief and self-limited event that can usually be supported with the use of positive-pressure ventilation. Administer succinylcholine at a dose of 1 to 2 mg/kg intravenously or 4 to 5 mg/kg intramuscularly. Support the patient's airway and provide airway management if laryngospasm is severe or persistent.

TABLE 159-7 Adult PSA Discharge Instructions

To best manage your condition, you were given medications that can cause drowsiness and clumsiness over the next several hours. While most of the effect has worn off by this time, your coordination and judgment may still be affected.

1. You should avoid all activities that could result in injury due to drowsiness or impaired coordination or judgment. Examples would include driving a motorized vehicle, operating machinery, biking, swimming, skating, or any activity at height where a fall could result.
2. The effects of the medications could cause you to feel weak, shaky, or even nauseated. You should rest during this time and wait 1–2 hours before trying small sips of liquids. You can increase to solid foods once you start feeling better.
3. Take additional pain medications as directed by the doctor.
4. For the next 24 hours, avoid taking anything that could make you drowsy. Examples would include alcohol, sleeping pills, and antihistamine medications.

Please call the Emergency Department if you have any questions or feel anything is unusual about your recovery.

Legend:

(A) Safety established in human studies

(B) Presumed safe based on animal studies

(C) Uncertain safety, animal studies show adverse effects, no human studies

(D) Unsafe

(+) Generally accepted as safe

(–) Generally regarded as safe

(?) Safety unknown or controversial

Virtually all agents can induce nausea and vomiting.^{3,118} Patients with recent oral intake are at a higher level of risk for aspiration.¹¹⁸

Always have suction available in case it is required. Hypotension induced by opiates or benzodiazepines is responsive to fluid management and the corresponding reversal agent. Chest wall rigidity from short-acting opioids that cannot be reversed with naloxone requires succinylcholine and airway management to support ventilation and oxygenation.

Allergic reactions can result from the administration of any of the medications. Management is like other allergic reactions in terms of treatment with epinephrine, diphenhydramine (i.e., an H₁ antagonist), an H₂ antagonist, and methylprednisolone.

The use of PSA in pregnant and lactating patients must be undertaken with great caution. The safety of many of the agents is unknown or of concern (Table 159-8). Consult an Anesthesiologist, Gynecologist, or Obstetrician prior to performing PSA on pregnant and lactating women.

SUMMARY

PSA is a necessary part of Emergency Medicine practice. Skillful application in the appropriate clinical scenarios will result in relief of patients' anxiety and pain. We have the necessary pharmaceuticals to control patients' pain and anxiety. It is essential to possess the knowledge and training to understand each patient's needs and satisfy this requirement with a careful risk-benefit assessment and appropriate drug selection. It is essential to maintain the necessary high standards to safely get the patient through these procedures with a minimum of risk and complications. Competency extends beyond the Emergency Physician and includes nursing and support personnel. They too must be knowledgeable as to the content of procedural sedation and analgesia with an uneventful recovery.

Everyone must know their limitations. Become very comfortable with a limited set of medications that will enable one to address

95% of all PSA requirements. Secure the assistance of a colleague or backup from an Anesthesiologist in difficult situations. PSA will never be a substitute for a little patience and a soft, gentle manner. Reserve PSA use for the patient who truly needs the intervention.

Ultrasound in Early Pregnancy

Srikar Adhikari, Wes Zeger, and Lori Stolz

INTRODUCTION

Abdominal pain and vaginal bleeding are common complaints of patients presenting to the Emergency Department (ED) in the first 20 weeks of pregnancy. Ectopic pregnancy is the most common life-threatening emergency during the first trimester of pregnancy. The current incidence of ectopic pregnancy is difficult to estimate from existing data.¹⁻³ The overall incidence of ectopic pregnancy has increased during the mid-twentieth century due to increased occurrence of pelvic inflammatory disease.¹⁻³ History and physical examination have proven to be unreliable in excluding the presence of an ectopic pregnancy. Pelvic ultrasound (US) is the diagnostic test of choice in the initial evaluation of these patients with possible ectopic pregnancy.

Emergency Physicians have been using bedside pelvic US in the evaluation of first-trimester pregnancy symptoms for more than a decade.⁴ Prior studies have demonstrated that ED pelvic US

decreases cost, patient length of stay, and morbidity.⁵⁻⁷ The main goal of ED pelvic US is to identify an intrauterine pregnancy (IUP). An IUP is identified 60% to 70% of the time on bedside US in women presenting with abdominal pain and/or vaginal bleeding to ED.⁸ The accuracy of pelvic US performed by Emergency Physicians for identifying an IUP has been well established.⁹⁻¹¹ The scanning skills of Emergency Physicians have extended beyond just identifying an IUP to diagnosing ectopic pregnancy using bedside US with increasing experience.¹²

ANATOMY AND PATHOPHYSIOLOGY

The pelvic cavity extends from the iliac crests superiorly to the pelvic diaphragm inferiorly. The female pelvis consists of the genital tract (i.e., vagina, uterus, and uterine tubes), ovaries, urinary bladder, a portion of the ureters, lower intestinal tract, pelvic musculature, ligaments, and peritoneal spaces.

The uterus is an oval, hollow, muscular, and pear-shaped extra-peritoneal organ located in the pelvis between the urinary bladder anteriorly and the rectum posteriorly (**Figure 160-1**). It is divided anatomically into the fundus, the body, the isthmus, and the cervix. The central cavity of uterus opens into a fallopian tube on either side and into the vagina below. The uterus is usually anteverted

A

B

FIGURE 160-1. Anatomy of the normal female pelvis. **A.** Midline sagittal CT view. **B.** Transverse view.

(i.e., pointing forward toward the anterior abdomen) and anteфлекed (i.e., flexed forward over the bladder). It may be retroverted (i.e., pointing back toward the spine) and retroфлекed (i.e., flexed away from the bladder) in some patients. The long axis of the uterus rarely lines up exactly with the long axis of the body. Most often it is found angled to one side. The size of the uterus is variable depending on the patient's parity, pubertal stage, and age. A postpubertal adult female uterus is approximately 8 cm long, 5 cm wide, and 3 cm deep. The endometrial canal is formed by the central, linear, and opposing surfaces of the walls of the endometrial cavity. The endometrial canal continues as the endocervical canal inferiorly. The vagina extends from the cervix to the external genitalia. It lies between the urinary bladder and the rectum (**Figure 160-1A**).

The fallopian tubes are bilateral coiled muscular tubes located lateral to the uterus (**Figure 160-1B**). They are anteromedial to the ovaries and posterior to the urinary bladder. Each fallopian tube is approximately 10 cm in length and 3 mm in diameter. The fallopian tube is divided into four anatomic segments from proximal to distal (i.e., interstitial, isthmus, ampulla, and infundibulum).

The ovaries are bilateral almond-shaped structures that measure approximately 4 cm in length, 3 cm in width, and 2 cm in height. The size of the ovaries varies depending on the patient's age, menstrual status, and menstrual cycle phase. They are quite mobile and their position is variable. They are most often identified posterolateral to the uterus against the pelvic side walls and just anteromedial to the internal iliac vessels within the adnexa (**Figure 160-1B**).

The female pelvis has an anterior cul-de-sac and a posterior cul-de-sac (**Figures 160-1A and 160-1B**). The anterior cul-de-sac or vesicouterine pouch is the peritoneal space between the anterior wall of the uterus and urinary bladder. The posterior cul-de-sac or pouch of Douglas is the area between the uterus and the rectum. **The posterior cul-de-sac is the most dependent area of the peritoneal sac. A small amount of free fluid in the posterior cul-de-sac is a normal physiologic finding. Physiologic free fluid in the pelvis of a pregnant patient is rare. A large amount of fluid in the posterior cul-de-sac is considered abnormal. Any amount of fluid identified in the anterior cul-de-sac is also considered abnormal.**

INDICATIONS

The indications to perform a pelvic US examination during early pregnancy include abdominal pain, back pain, dizziness, hypotension, a pelvic mass, pelvic pain, syncope, tachycardia, trauma, or vaginal bleeding on physical examination.

CONTRAINDICATIONS

There are no absolute contraindications for a pelvic US during early pregnancy. A recent pelvic surgical procedure is a relative contraindication. Always perform a bimanual or speculum examination before performing an endovaginal US examination. Use caution when performing an endovaginal US examination if the cervical os is open. **The US transducer should never enter the endocervical canal or the uterus.**

EQUIPMENT

- US machine
- Low-frequency 5-2 MHz curvilinear transducer (**Figure 160-2A**)
- High-frequency 9-4 MHz endocavity transducer (**Figure 160-2B**)
- Condom or US transducer sheath, nonlatex preferable
- US gel

A

B

FIGURE 160-2. US transducers or probes used in pelvic ultrasonography. **A.** Curvilinear transducer. **B.** Endocavitary transducer.

PATIENT PREPARATION

Obtain a relevant history from the patient prior to performing an US examination. It should include current symptoms, date of last menstrual period, use of fertility agents, assisted reproductive technology, gravidity, parity, complications of prior pregnancies, and prior pelvic surgeries. Use a nonlatex condom or transducer sheath for the US examination if the patient is allergic to latex. Discuss with the patient what the US examination entails and obtain verbal consent. **A sonographer should always be accompanied by a chaperone when performing a transvaginal US examination.**

A full urinary bladder is essential for a transabdominal US examination. The full bladder displaces bowel loops from the pelvis and provides an acoustic window to visualize the underlying pelvic organs. An excessively distended bladder can compress or displace the pelvic structures out of view. If this happens, instruct the patient to partially empty their bladder. **Transvaginal US requires an empty urinary bladder.** A distended bladder displaces the uterus and ovaries, creates artifacts, and makes it difficult to visualize the pelvic structures.

TECHNIQUES

TRANSABDOMINAL SONOGRAPHY

Two approaches are used to perform a pelvic US examination of an early pregnancy.⁴ Transvaginal sonography (TVS) is used for most cases in conjunction with transabdominal sonography (TAS). Both techniques provide complimentary information. TAS usually precedes TVS while the patient has a full bladder. TAS helps define the spatial orientation of the pelvis. The field of view is larger with TAS compared to TVS. TAS allows better visualization of the relationship of the uterus with adjacent pelvic and abdominal structures. Hemoperitoneum and large pelvic masses that extend outside of the true pelvis are better visualized with TAS. **TVS is not required if the TAS provides adequate information to make a diagnosis.**

TAS OF THE UTERUS AND VAGINA IN THE SAGITTAL PLANE

A low-frequency 5-2 MHz curvilinear transducer is typically used for TAS. It can be performed using a low-frequency 5-1 MHz phased array transducer if a curvilinear transducer is not available. Visualize the uterus and adnexal structures in both the sagittal (i.e., longitudinal) and transverse (i.e., cross-section or short) planes. Place the patient supine. Apply US gel to the suprapubic area and to the footprint of the transducer. Begin scanning in a sagittal or longitudinal plane by placing the transducer just above the pubic symphysis. Aim the transducer indicator toward the patient's head (Figure 160-3). The indicator on the transducer corresponds with the left side of the screen and cephalad structures are seen on the left side of the image in the sagittal plane (Figure 160-4).

A

B

FIGURE 160-3. Sagittal view of TAS. **A.** Transducer positioning. The arrow indicates the direction of the indicator. **B.** The US beam is directed through the anatomic structures in the midsagittal plane. (Courtesy of Stephen Leech, MD.)

A

B

FIGURE 160-4. Sagittal view of a nonpregnant uterus by TAS. **A.** The US image. **B.** Corresponding anatomic diagram. (Courtesy of Stephen Leech, MD.)

Identify the uterus and vagina in the sagittal or long axis (Figure 160-4). Note the position of the uterus and whether it is anteverted or retroverted. The shape and position of the uterus are extremely variable. The position changes depending on the amount of urine in the urinary bladder. Obesity and a retroverted position can make it difficult to identify the uterus. Identify each of the anatomic areas of the uterus (i.e., the fundus, the body, and the endometrial stripe).

The normal uterus has a sonographically low-gray homogenous texture (Figure 160-4A). The appearance of the uterine endometrium changes with the different phases of the menstrual cycle. The normal endometrial stripe or endometrial canal is visible as a thin and bright echogenic line in the middle of the uterus (Figure 160-4). The sonographic appearance of the endometrial stripe changes as the thickness of the endometrium changes cyclically with the menstrual cycle. Use the direction of the endometrial stripe to find the uterine position and determine if it is anteverted or retroverted. The cervix has a similar appearance to that of the uterus.

Adjust the transducer to visualize the uterine body and fundus in the same scanning plane with the vagina and cervix. Slide the transducer to the right and/or left of midline, angle the transducer toward the patient's feet, or combine both maneuvers until the vagina and cervix come into view. The vagina is visualized between the anechoic bladder anteriorly and the echogenic rectum

posteriorly (**Figure 160-4**). The muscular vaginal walls appear low gray and isoechoic to the uterine myometrium. The central mucosal lining of the collapsed vaginal canal walls appears thin, linear, and hyperechoic. The vagina is visible as a tubular extension of the uterus in the sagittal plane. It is flattened and oval shaped in the transverse plane. The rectum usually has air and fecal material casting a posterior acoustic shadow in the far field of the image. The bladder is always visualized in the right upper corner of the image in transabdominal view. A fully distended bladder is visible as an anechoic structure with hyperechoic walls anterior to the uterus in the near field of the image (**Figure 160-4**). The bladder cavity will not be visible if it is empty and collapsed.

Twist the transducer varying degrees to align the long axes of the uterus, vagina, endometrial canal, endocervical canal, and vaginal canal. Move the transducer from side-to-side through the entire width of the uterus in the transverse plane looking for evidence of an IUP. Determine the long axis of the uterus and vagina. Sweep the transducer from left-to-right and right-to-left to scan through and beyond the lateral boundaries of the uterus, adnexa, and pelvic side walls on both sides. Note the location of the ovaries if they are visualized. **The uterus serves as the reference point for other pelvic structures.** It might be necessary to apply firm pressure with the US transducer to the patient's abdominal wall to displace bowel gas and improve image quality.

TAS OF THE UTERUS AND VAGINA IN THE TRANSVERSE PLANE

Rotate the US transducer 90° counterclockwise to scan in the transverse plane (**Figure 160-5**). The transducer indicator will be aimed toward the patient's right side. The transducer indicator and the marker on the screen are aimed in the same direction. Angle the transducer inferiorly to identify the transverse section of the vagina between the bladder anteriorly and the rectum posteriorly. Adjust the transducer as necessary to identify the vaginal canal. Angle the transducer inferiorly and scan through and beyond the margins of the vagina and pelvic cavity. Slowly straighten the transducer back to the perpendicular position. Continue scanning superiorly through and beyond the margins of the vagina and onto the cervix.

The transverse section of the cervix will appear slightly larger than the vagina. Adjust the transducer to visualize the endocervical canal.

Keep the transducer perpendicular and angle it further superiorly to scan through and beyond the cervix and onto the uterine body (**Figure 160-6**). The body of the uterus will appear larger than the cervix. Twist the transducer gently to visualize the centrally located endocervical canal. Continue to scan superiorly through the body of the uterus and onto the fundus. The transverse section of the uterine fundus will appear slightly larger than the body. Adjust the transducer as necessary to visualize the centrally located endometrial canal. Angle the US transducer further superiorly through the fundus and urinary bladder walls up to the level of the umbilicus.

TAS OF THE OVARIES AND ADNEXA

Normal ovaries are often not visualized with TAS. They are relatively small and hidden by bowel gas or other pelvic structures with similar echogenicity. The location and lie of the ovaries are quite variable. The long axis of the ovary can lie within either scanning plane, transverse or sagittal. The ovaries are usually found lateral to the body or fundus of the uterus. Sweep laterally from the uterus in both planes to find the ovaries. Look for the greatest dimension of the ovary regardless of the transducer position. The greatest dimension may be in the transverse, sagittal, or oblique plane. Determine the volume of the ovary by measuring the length, width, and height using views obtained in two orthogonal planes. Blood vessels can be confused with ovarian follicles. Rotate the transducer 90° and determine if the structure becomes "tube-like." If so, it is most likely a blood vessel. Doppler can help to make this distinction.

It is difficult to thoroughly evaluate the adnexa on TAS. The ovaries can serve as landmarks for assessing adnexal pathology. Survey the adnexa for abnormalities such as masses and dilated tubular structures. If an abnormality is found in the adnexa, note its size, sonographic appearance, and relationship to the uterus and ovaries.

Evaluate the cul-de-sac for free fluid, a hematoma, or a mass in the sagittal and transverse planes. Fluid in the cul-de-sac is visible as an anechoic area. Note the echogenicity of the fluid. If a mass is visualized, note its size, shape, location, sonographic appearance, and relationship to the ovaries and uterus. Bowel can look like a pelvic

FIGURE 160-5. Transverse view of a nonpregnant uterus by TAS. **A.** Transducer positioning. **B.** The US beam is directed through the anatomic structures in the transverse plane. The arrow indicates the direction of the indicator. (Courtesy of Stephen Leech, MD.)

A

B

FIGURE 160-6. Transverse view of a nonpregnant uterus by TAS. **A.** The US image. **B.** Corresponding anatomic diagram. (Courtesy of Stephen Leech, MD.)

mass, an ovary, or a dilated fallopian tube. Hold the US transducer still over the structure and observe it for signs of peristalsis to distinguish a bowel loop from other structures. Differentiation of normal bowel loops from a mass may be difficult by TAS. TVS might help to differentiate a suspected mass from fluid and fecal material within the normal rectosigmoid colon.

TRANSVAGINAL SONOGRAPHY

TVS is necessary after TAS when pelvic structures require further evaluation, structures are not visible on TAS, or the TAS is inconclusive.¹³ Instruct the patient to void after completing the TAS and then perform the TVS. The endocavity transducer is placed closer to pelvic structures when compared to TAS. TVS provides more anatomic detail of pelvic organs than TAS, especially adnexal structures. It provides images of pelvic structures with higher resolution, allowing the early identification of intrauterine contents and adnexal abnormalities.

Place the patient in the lithotomy position. This position allows for a full range of movement of the endocavity US transducer. TVS is best performed with an empty bladder following the speculum and bimanual examination to minimize patient discomfort. Remove any tampons in the vagina during the speculum examination. Note any vaginal or cervical lesions, vaginal wounds, bulging membranes through the cervix, or if the cervical os is open. Explain the procedure and verbally consent the patient regarding the examination.

FIGURE 160-7. Endocavity transducer preparation. US gel is first applied to the footprint of the transducer before it is inserted into the sheath cover. Additional US gel is then applied to the distal end of the sheath cover.

A high-frequency 9-4 MHz endocavity transducer is used for TVS. Apply US gel to the footprint of the transducer and cover it with a condom or transducer sheath (**Figure 160-7**). Smooth all the air bubbles away from the footprint of the transducer by running a finger over the condom or transducer sheath covering the distal end of the transducer. This ensures smooth transmission of the US beam and prevents imaging artifacts. Apply additional US gel to the outside of the condom or transducer sheath before inserting the transducer into the patient's vagina.

TVS requires viewing the uterus and other pelvic structures in the sagittal and transverse planes. Each structure must be scanned left to right in the sagittal plane and up and down in the transverse plane. Image orientation in TVS can be challenging due to the narrow field of view, the inferior scanning approach, and variations in the position of the pelvic organs. **It is important to determine the proper position of the US transducer before inserting it into the vagina.** Aim the transducer indicator toward the ceiling to scan in the sagittal plane. Rotate the transducer 90° counterclockwise with the indicator aimed toward the patient's right side to scan in the transverse plane.

TVS OF THE UTERUS AND VAGINA IN THE SAGITTAL PLANE

Gently insert the US transducer downward and backward into the lower third of the vagina with the indicator directed toward the ceiling (**Figure 160-8**). This will position the US transducer adjacent to the cervix (**Figure 160-8B**). Start scanning by slowly lowering the handle toward the floor to view the fundus of the uterus in the sagittal plane. The fundus of an anteverted uterus will be on the left side of the screen pointing toward the anterior abdominal wall (**Figure 160-9**). A retroverted uterine fundus will be on the right side of the screen pointing in the direction of the posterior abdominal wall (**Figure 160-10**). To completely visualize the retroverted

A

B

FIGURE 160-8. Sagittal view of a nonpregnant uterus by TVS. **A.** Transducer positioning. The arrow indicates the direction of the indicator. **B.** The US beam is directed through the anatomic structures in the sagittal plane. (Courtesy of Stephen Leech, MD.)

uterus, lift the US transducer handle toward the ceiling, moving the US transducer tip posteriorly and inferiorly.

Move the transducer side to side and vice versa to evaluate the centrally located endometrial canal and lateral margins. Any urine

FIGURE 160-9. TVS of an anteverted uterus in the sagittal plane.

FIGURE 160-10. TVS of a retroverted uterus in the sagittal plane.

in the bladder will be visible in the left upper corner of the screen (**Figure 160-11**). Slowly lift the US transducer handle toward the ceiling to visualize the body of the uterus and the cervix. Continue moving the US transducer side to side to evaluate the lateral margins, the centrally located endometrial canal, and the endocervical canal. It may be necessary to slightly rotate or twist the US transducer to fully visualize the long axis of the uterus and the entire endometrial stripe (**Figure 160-11**). Thoroughly screen for any intrauterine contents. Note the contents, if any, of the posterior cul-de-sac at the level of uterine fundus, uterine body, and the cervix. **The goal is to scan the entire uterus from right to left through its entire length.**

TVS OF THE ADNEXA IN THE SAGITTAL PLANE

Continue scanning sagittally to the adnexal areas after scanning the uterus in the sagittal plane. Lower the US transducer handle and identify the fundus of the uterus. Move the US transducer handle toward the patient's left thigh to scan through the right adnexa. This movement directs the US beam toward the right adnexal region. Return the US transducer to the midline and reidentify the fundus. Move the US transducer handle toward the patient's right thigh to scan through the left adnexa. This movement directs the US beam toward the left adnexal region. Repeat these lateral sweeps through the adnexal areas at the levels of the uterine body and cervix. The uterus serves as the reference point for other pelvic structures while performing the pelvic US examination.

TVS OF THE UTERUS AND VAGINA IN THE TRANSVERSE PLANE

Scan in the transverse plane after completing TVS in the sagittal plane. Turn the US transducer 90° counterclockwise from the sagittal plane (**Figure 160-12**). The US transducer indicator will be directed toward the patient's right side. The orientation in this plane is like a computed tomography (CT) scan image. The left side of the US image corresponds to patient's right side (**Figure 160-13**). Begin scanning by slowly lowering the handle of the US transducer toward the floor. Identify the uterine fundus and the endometrial stripe. Continue to scan until completely through the uterus. Slowly lift the US transducer handle toward the ceiling to scan the entire length of the uterus, the cervix, and the posterior cul-de-sac.

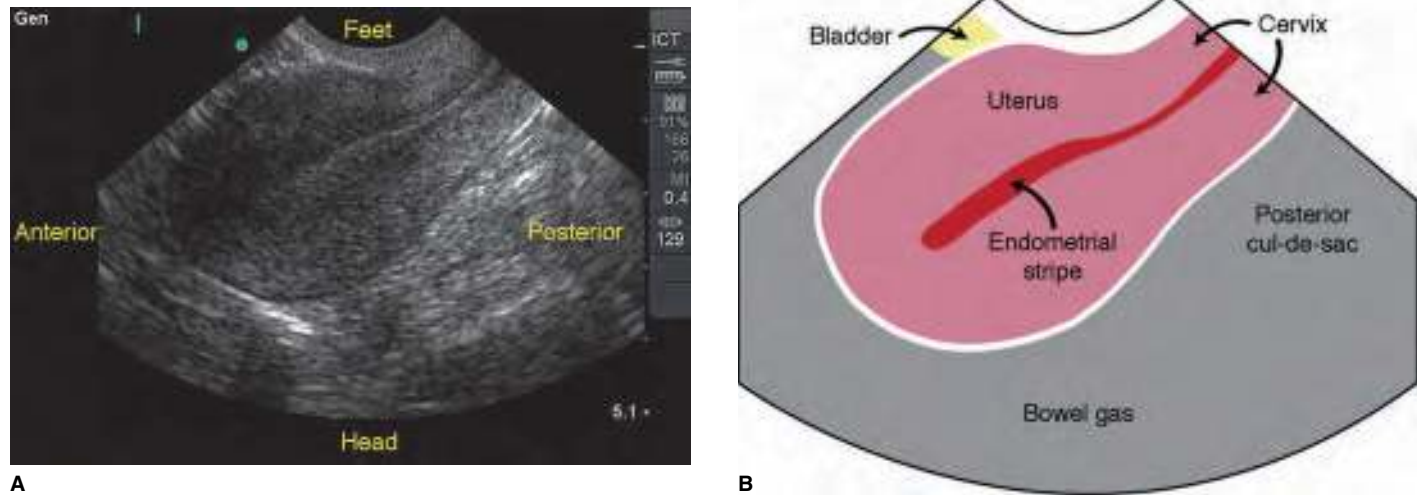

FIGURE 160-11. Sagittal view of a nonpregnant uterus by TVS. **A.** The US image. **B.** Corresponding anatomic diagram. (Courtesy of Stephen Leech, MD.)

FIGURE 160-12. Transverse view of a nonpregnant uterus by TVS. **A.** Transducer positioning. The arrow indicates the direction of the indicator. **B.** The US beam is directed through the anatomic structures in the transverse plane. (Courtesy of Stephen Leech, MD.)

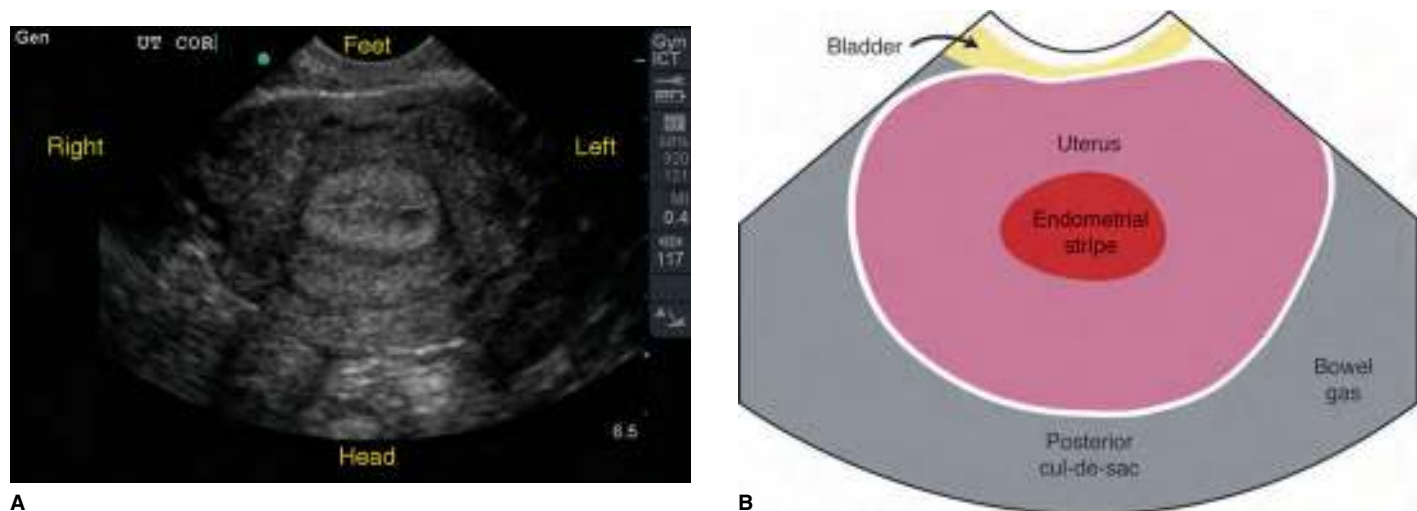

FIGURE 160-13. Transverse view of a nonpregnant uterus by TVS. **A.** The US image. **B.** Corresponding anatomic diagram. (Courtesy of Stephen Leech, MD.)

TVS OF THE OVARIES IN THE TRANSVERSE PLANE

The ovaries are best visualized in the transverse plane while scanning the adnexal regions transvaginally. Keep the uterus to one side of the image and scan up and down on each side of the uterus to locate the ovaries. The ovaries appear hypoechoic to the uterine myometrium with a mid-to-low gray echogenicity. The periphery of the normal ovary represents the tunica and is hypoechoic. The stroma is visualized as a low-gray echogenic center. Ovarian follicles in the periphery are small, round, and anechoic structures that vary in size and number. The sonographic appearance, size, and location of the ovaries vary greatly depending on the patient's age, menstrual phase, and pregnancy status. Identify iliac blood vessels. The ovaries are usually located lateral to the uterus and anteromedial to the iliac vessels (**Figure 160-14**). When the ovary is identified, scan through the margins by moving the US transducer handle up and down as necessary.

Rotate the US transducer 90° and sweep the beam anterior to posterior to visualize the ovaries and obtain the longest dimension of the ovary. The iliac vessel can serve as landmark to obtain the longest length of the ovary. Measure the size of the ovary by obtaining the three longest dimensions of the ovary (i.e., width, length, and height) in two orthogonal planes. Note any abnormalities of the

A

B

FIGURE 160-14. Transverse view of a normal ovary by TVS. **A.** The ovary is seen medial to the iliac vessel. **B.** Follicles are seen in the periphery of the ovary (arrows).

ovary. The ovaries may not be identifiable in the presence of a large leiomyoma, in prepubertal females, and in postmenopausal females. The fallopian tubes are not routinely visible on US unless filled with fluid, filled with pus, or outlined by free intraperitoneal fluid.

TVS OF THE ADNEXA IN THE TRANSVERSE PLANE

After scanning the uterus and ovaries, continue the transverse scanning through the left and right adnexal regions. Identify the uterine fundus. Sweep the US transducer handle toward the patient's left thigh to visualize the right adnexa. Slowly move the US transducer handle from the floor toward the ceiling to sweep through the entire right adnexal area. Return the US transducer to the midline and reidentify the uterine fundus. Sweep the transducer handle toward the patient's right thigh to visualize the left adnexa. Survey the adnexal regions for any masses or dilated tubular structures. If an abnormality is found in the adnexa, note its size, sonographic appearance, and relationship to the ovaries and uterus. Doppler mode may be useful to evaluate any adnexal abnormalities and to help determine if the structure is vascular or if there is a heartbeat.

Survey the anterior and posterior cul-de-sacs thoroughly for free fluid, hematomas, or masses in the sagittal and longitudinal planes. Note the echogenicity of the fluid. If a mass is visualized, scan it in two orthogonal planes. Note its size, shape, location, sonographic appearance, and relationship to the ovaries and uterus. TVS is very helpful to differentiate a suspected mass from fluid and fecal material within the normal rectosigmoid colon. Distinguish bowel loops from other structures. Posterior cul-de-sac fluid can be quantified into small, moderate, and large in volume.¹⁴ Free fluid seen less than one-third of the way up the posterior wall of the uterus is classified as small (**Figure 160-15**). Free fluid seen two-thirds of the way up the posterior wall of the uterus is classified as moderate (**Figure 160-16**). Free fluid seen over two-thirds of the way up the posterior wall of the uterus is classified as large (**Figure 160-17**).

FIRST-TRIMESTER ULTRASOUND

Approximately 70% of first-trimester patients seen in the ED will have an IUP visualized with US.¹⁵ **First determine if the patient has an IUP when evaluating a patient with pain or bleeding in the first trimester of pregnancy.** A high-frequency 12-3 MHz linear transducer can be used for transabdominal sonography to identify an IUP after a failed examination with a low-frequency 5-2 MHz curvilinear transducer. It provides greater resolution of smaller structures and may identify a yolk sac or embryo not detected with

FIGURE 160-15. A small amount of free fluid in pelvis (arrows).

FIGURE 160-16. A moderate amount of free fluid in pelvis (arrows).

a curvilinear transducer. Determine the number of fetuses, their viability, and the gestational age if an IUP is visualized. **If an IUP is not visualized, scan the pelvis thoroughly and look for any signs of an ectopic pregnancy.** The introduction of fertility treatments has increased the incidence of heterotopic pregnancy (i.e., simultaneous intrauterine and ectopic pregnancy) and multiple intrauterine gestations.¹⁶ TVS is generally not performed if an IUP is found on TAS and the patient is not undergoing any fertility treatment. **Perform TVS if an IUP cannot be confirmed using TAS or evaluate other causes of pelvic pain including ovarian torsion.**

NORMAL IUP

Early gestational structures are generally visualized 7 to 10 days earlier using TVS compared to TAS. **Systematically look for the sonographic findings of an IUP as discussed in the following sections.**

THE GESTATIONAL SAC

A gestational sac is an anechoic fluid collection within the uterus surrounded by a ring of bright, thick, and symmetric echogenic tissue (Figure 160-18). It is clearly visible at 5 weeks of gestation by TVS. The gestational sac is approximately 5 mm in diameter at 5 weeks and grows at a rate of 1 mm/day. **A gestational sac is not**

FIGURE 160-17. A large amount of free fluid in pelvis (arrows).

a definite sign of an IUP. Determine the number and location of the gestational sac(s). Evaluate the gestational sac(s) in two orthogonal planes. Note the outline, shape, and contents of the gestational sac(s). The normal gestational sac is a round, centrally located, smooth-walled structure (Figure 160-18). Suspect a hematoma formation if the structure is irregular in outline and collapsing. The echogenic tissue surrounding the gestational sac represents developing chorionic villi and the adjacent endometrium. It should be thicker and echogenically brighter than the myometrium.

The size of the gestational sac can be used for gestational dating. The most commonly used method is the mean sac diameter (MSD) method. Obtain the longest three measurements in millimeters of the length, width, and height of the gestational sac in two orthogonal planes. Do not include the echogenic rim of trophoblastic and decidual tissue surrounding the gestational sac. Obtain the measurements from the inner margin to the inner margin of the gestational sac. The MSD is calculated by the following equation: $MSD = (length + width + height) \div 3$. The gestational age is calculated by the following equation: $gestational\ age\ (days) = MSD\ (mm) + 30$.

THE DOUBLE DECIDUAL SIGN

Two concentric echogenic rings surrounding a gestational sac form the double decidual sign (Figure 160-19).^{17,18} The outer bright ring is called the decidua vera and is formed by the endometrial lining of the uterus (i.e., the decidua). The inner echogenic ring is called decidua capsularis and is formed by the chorion surrounding the gestational sac. The two bright layers are separated by a hypoechoic or anechoic layer of fluid which is the endometrial canal. **The double decidual sign is highly suggestive of an IUP but is not 100% reliable.¹⁹ It occurs in only about half of all intrauterine pregnancies.**

THE YOLK SAC

The yolk sac is the first embryonic structure seen within the gestational sac (Figures 160-18 and 160-19). **It is the earliest reliable US sign of an IUP. The presence of a yolk sac within the gestational sac in the uterus is diagnostic for an IUP.** The normal yolk sac is round with an anechoic fluid-filled center and measures less than 7 mm in diameter. The yolk sac is visualized as a bright, spherical, thin-walled structure within the gestational sac with a balloon on a string appearance (Figures 160-18 and 160-19). It is visible when the gestational sac is > 8 mm by TVS and > 20 mm by TAS. The yolk sac is usually visible 5 to 6 weeks after the last menstrual period by TVS and at 7 weeks by TAS. Measure the yolk sac from its inner margin to its opposite inner margin. It generally disappears after 10 to 12 weeks but can persist until 20 weeks.

THE EMBRYO

The embryonic or fetal pole is visible at 5 to 6 gestational weeks by TVS. It is approximately 1 to 2 mm in length at 5 to 6 weeks of gestation. The normal embryo grows at a rate of 1 mm/day. It appears as a highly echogenic focal thickening adjacent to the yolk sac, hugging the wall of the gestational sac surrounded by anechoic fluid (Figure 160-18A). The embryo is visible within the gestational sac when the MSD is between 5 and 12 mm by TVS. **The presence of a fetal pole within the gestational sac in the uterus is diagnostic for an IUP.** Measure the fetal pole along its longest axis.

FETAL CARDIAC ACTIVITY

Fetal cardiac activity is visible by 6.5 weeks of gestation and a fetal pole size of 6 mm by TVS. Fetal cardiac activity is generally visible by TAS in embryos > 10 mm long. A faint fluttering motion within the fetal pole adjacent to the yolk sac represents the neurologically

A

D

active heart tissue. **The presence of fetal cardiac activity inside the uterus is diagnostic for a live IUP.** The incidence of a miscarriage, or spontaneous abortion, before 20 weeks of gestation with a live IUP diagnosed on US in the ED is 9.2%.²⁰ Use M-mode to determine the fetal heart rate (FHR). It is calculated by measuring the

length of one cycle and then determining the cycles per second from that measurement (**Figure 160-20**). The normal FHR for an embryo > 6 mm in length is over 120 beats/min. FHR serves as an important prognostic indicator. Rates less than 90 beats/min are associated with a high risk of spontaneous abortion.

A

B

FIGURE 160-19. Sagittal view of an early pregnancy by TVS. **A.** Double decidual sign. **B.** A gestational sac (yellow arrows) contains a yolk sac (red arrows) and a fetal pole (FP) within the endometrium (green arrows). (Photo used with permission from www.aliem.com.)

FIGURE 160-20. Fetal heart rate measurement using M-mode.

ESTIMATING FETAL AGE

The crown-rump length (CRL) is the most accurate sonographic measurement for gestational dating between 7 and 10 weeks.²¹ It is accurate within ± 3 days for gestational dating. The embryonic pole length is used for the CRL measurement. By 8 weeks, a true CRL measurement can be determined. Obtain the longest measurement of an unflexed fetus and do not include the yolk sac (Figure 160-21A). The gestational age is calculated by the following equation when CRL is < 25 mm: gestational age (days) = CRL (mm) + 42.

The CRL cannot be seen and measured accurately during some US scans. The biparietal diameter (Figure 106-21B) and/or femur length (Figure 160-21C) can be measured. Measure the biparietal diameter perpendicular to the central fissure at the level of the thalamic nuclei. Measure the femur length from the two blunted ends. Do not include the extension to the greater trochanter and the femoral head. The measurement is considered inaccurate when the femur image is at an angle of over 30° to the horizontal. Compare these values to standardized tables to determine the fetal age. Some US machines have these tables built in. A click of a button or two is all it takes.

CORPUS LUTEAL CYST

The corpus luteum is a normal physiologic structure found within one of the ovaries during pregnancy. It is unilocular and thin-walled. The sonographic appearance of a corpus luteum is highly variable. It can appear as a hypoechoic, hyperechoic, or isoechoic structure. Power Doppler mode shows the corpus luteum has increased blood flow at the periphery that is described as a “ring of fire” (Figure 160-22). The ring of fire is visible with an ectopic pregnancy.

EMBRYONIC DEMISE OR EARLY PREGNANCY FAILURE

Definitive diagnosis of an early pregnancy failure requires serial US examinations. A blighted ovum is a failed pregnancy in which the embryo failed to develop within a gestational sac of sufficient size that an embryo should be visible. There are several sonographic findings that can suggest early pregnancy failure. The earliest sign of early pregnancy failure is a gestational sac without a yolk sac or embryo. An empty gestational sac with a MSD ≥ 25 mm and no evidence of an embryo or yolk sac by TVS is diagnostic of pregnancy failure (Figure 160-23A).²² A CRL of ≥ 7 mm without a fetal heart rate is also diagnostic of pregnancy failure (Figure 160-24). Other findings that are suggestive but not diagnostic of embryonic demise include a MSD between 16 and 24 mm by TVS without an embryo,

A

B

C

FIGURE 160-21. Determining the age of an embryo. **A**. Crown-rump length. Maximal embryo length is measured (dotted line) and excludes the yolk sac. **B**. Biparietal diameter measured perpendicular to the central fissure (arrow) and through the thalamic nuclei (arrowheads). (Photos used with permission from reference 4.) **C**. Femur length measurement (between +’s).

a CRL of < 7 mm by TVS without a fetal heartbeat, an enlarged yolk sac (i.e., > 7 mm), and a small gestational sac in relation to the size of the embryo (i.e., < 5 mm difference between mean sac diameter and CRL).²²

FIGURE 160-22. Corpus luteum cyst with the ring of fire visualized on power Doppler mode.

Additional signs suggestive of early pregnancy failure include a gestational sac that is irregular in shape, distorted, or collapsed (**Figure 160-23B**). A gestational sac positioned low in the uterine cavity or surrounded by a thin (i.e., < 2 mm) wide decidual reaction indicates embryonic demise. Absence of a yolk sac when an embryo is visualized prior to 12 weeks is indicative of embryonic demise. A calcified yolk sac is associated with an adverse pregnancy outcome.

A

B

FIGURE 160-23. Sagittal view of an early pregnancy failure by TVS. **A.** The gestational sac is 25 mm in diameter (dotted line) without a visible yolk sac or embryo. **B.** An irregular gestational sac.

FIGURE 160-24. Embryonic demise. Note the absence of fetal cardiac activity on M-mode. (Courtesy of Sam Hsu, MD).

Embryonic bradycardia (i.e., < 90 beats/min) is associated with a poor prognosis.

SPONTANEOUS ABORTION

A spontaneous abortion is the most common complication of first-trimester pregnancy and occurs in approximately 20% of clinically apparent pregnancies.²³ An empty uterus with a clear midline echo occurs on US after a complete spontaneous abortion. An incomplete abortion is visible on US as irregular echogenic material within the uterine cavity (**Figure 160-25A**) or a thickened midline stripe ≥ 10 mm wide within the uterine cavity (**Figure 160-25B**). These both represent retained products of conception.

SUBCHORIONIC HEMORRHAGE

A subchorionic hemorrhage is bleeding between the chorion and the uterine endometrium. It can cause sudden pelvic pain or vaginal bleeding. The overall incidence in pregnancy is 1.3%. It results in the chorionic membrane separating and elevating from the decidua vera (i.e., endometrium) by a hematoma or clot. The acute hemorrhage appears hyperechoic or isoechoic. The hematoma becomes hypoechoic or anechoic as it undergoes liquefaction during the subsequent 1 to 2 weeks (**Figure 160-26**).

There is an increased risk of miscarriage, stillbirth, abruption, preterm premature rupture of membranes, and preterm labor in patients with a subchorionic hemorrhage. In a retrospective study done by Bennet et al, the overall pregnancy loss rate was 9.3%.²⁴ A large meta-analysis demonstrated that the odds ratio of spontaneous abortion in pregnant women found to have a subchorionic hematoma was 2.18.²⁵ This was found to increase with increasing maternal age and decreasing gestational age. The prognosis depends upon the size of the subchorionic hemorrhage. Small and medium-sized hemorrhages, up to approximately 50% of the gestational sac circumference, have a spontaneous abortion rate of 9%. Hemorrhages larger than 50% of the gestational sac circumference have a spontaneous abortion rate of 18.8%. Hemorrhages > 40% of the volume of the gestational sac are associated with spontaneous abortion rates of 50%.

ECTOPIC PREGNANCY

The prevalence of ectopic pregnancy among patients presenting to the ED with bleeding, pain, or both during first trimester is 6% to 16%.²⁶ **Clinical criteria alone are not sufficient to distinguish**

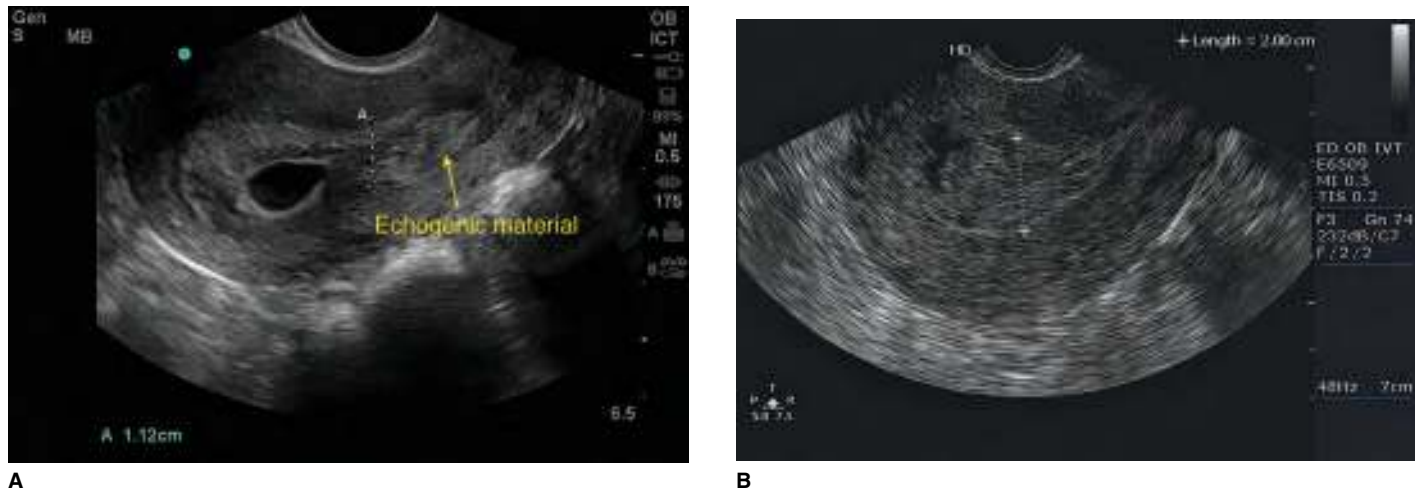

FIGURE 160-25. Sagittal view of an incomplete spontaneous abortion by TVS. **A.** Irregular echogenic material in the endometrial canal without evidence of a fetus. **B.** Thickened endometrial stripe (dotted line) without evidence of a fetus.

between a patient having a spontaneous abortion and an ectopic pregnancy. Pelvic US is the diagnostic test of choice in the evaluation of a patient with a possible ectopic pregnancy. The risk of heterotopic pregnancy in the general population is 1 in 4000 to 1 in 30,000 pregnancies. The risk increases to 1% in women undergoing in vitro fertilization.^{23,27,28}

The discriminatory zone is the β -human chorionic gonadotropin (β -hCG) level at which an IUP should be seen by pelvic US. This level generally is between 1000 and 2000 mIU/mL by TVS and between 4000 and 6500 mIU/mL by TAS. Approximately 38% of patients with a confirmed ectopic pregnancy had a β -hCG level < 1000 mIU/mL. Approximately 39% of ectopic pregnancies with β -hCG levels less than 1000 mIU/mL can be identified on US.²⁹ The concept of a discriminatory zone becomes more significant if the US is indeterminate.

There is no β -hCG level that rules out an ectopic pregnancy in a pregnant patient. Correlate the serum β -hCG values with the US findings. Have a high suspicion for an ectopic pregnancy if the US findings are indeterminate and the serum β -hCG levels are above the discriminatory zone. Any pregnancy in which there is a detectable β -hCG value and no visualized IUP on US is considered a pregnancy of unknown location (PUL).

FIGURE 160-26. Sagittal (left) and transverse (right) views of a pregnant uterus by TAS showing a subchorionic hemorrhage (SCH). (Courtesy of Sam Hsu, MD.)

Approximately 95% of ectopic pregnancies occur in the fallopian tube. This is split into 80% in the ampulla, 10% to 15% in the isthmus, and < 2% in the interstitial region. The remaining 5% are found in the cervix, on the ovary, and in the abdomen. Approximately 31% of pregnant patients presenting to the ED have no definite signs of either an IUP or an ectopic pregnancy on US. The diagnosis of an ectopic pregnancy is often reached through a combination of abnormal US findings. The spectrum of sonographic findings of an ectopic pregnancy is broad and includes an empty uterus, a pseudogestational sac, an adnexal mass, an extrauterine empty gestational sac, an extrauterine gestational sac with a yolk sac, an embryo with or without cardiac activity, a tubal ring, and fluid in the cul-de-sac.

EMPTY UTERUS

An ectopic pregnancy should be suspected in any pregnant patient presenting with abdominal pain or vaginal bleeding. Perform TVS to determine if an IUP is present. The empty uterus is the lack of an IUP in a pregnant patient. This is referred to as a PUL. **An empty uterus is a sign of an ectopic pregnancy unless proven otherwise.**

PSEUDOGESTATIONAL SAC

A pseudogestational sac is the decidualization of the endometrium from hormonal stimulation by the ectopic pregnancy. It occurs in 10% to 20% of ectopic pregnancies. The pseudogestational sac is often < 10 mm in diameter and consists of endometrial fluid. The pseudogestational sac is distinguished from a normal gestational sac by its central location in the endometrial cavity, lack of a double decidual sign, an ovoid shape, and poorly defined margins (Figure 160-27). A normal gestational sac is eccentrically placed within the endometrial cavity.

EXTRAUTERINE GESTATIONAL SAC

An intact gestational sac with a yolk sac outside the uterus confirms an ectopic pregnancy (Figure 160-28). The most specific finding of an ectopic pregnancy is the presence of a live extrauterine pregnancy. This occurs in 3% to 26% of ectopic pregnancies and is characterized by fetal cardiac activity outside of the uterus.³⁰

ADNEXAL MASSES

Adnexal abnormalities occur in approximately 70% to 90% of ectopic pregnancies. **The sonographic appearances of these abnormalities are variable, often only suggestive, and not**

A

B

FIGURE 160-27. Examples of a pseudogestational sac. **A.** Sagittal view of a pseudogestational sac (arrows) by TVS. **B.** Empty fluid-filled sac within the endometrium. (Photo used with permission from www.aliem.com.)

A

FIGURE 160-29. An adnexal mass adjacent to the ovary by TVS. (Courtesy of Michael Blaivas, MD.)

diagnostic of an ectopic pregnancy. Abnormalities are frequently visible as spherical structures with increased blood flow on power Doppler, such as the ring of fire seen with a normal corpus luteum. The most common finding is a small noncystic mass with mixed echoes adjacent to the ovary (**Figure 160-29**). The corpus luteum is located on the same side as the ectopic pregnancy in 80% of cases (**Figure 160-30**). Adnexal masses next to the ovary can be difficult to distinguish from a normal corpus luteum. Apply pressure with the endocavitary US transducer to help separate the ectopic mass from the ovary. The Emergency Physician's hand can be used to palpate the abdomen and apply additional pressure to separate an adnexal mass from the ovary for improved visualization.³¹

TUBAL RING

The tubal ring is an extrauterine hypoechoic concentric mass with a thick-walled echogenic rim and separate from the ovary (**Figures 160-31 and 160-32**). It represents a gestational sac and the surrounding trophoblastic reaction. It is found in 68% to 78% of ectopic pregnancies. The presence of a tubal ring has a 95% positive predictive value for an ectopic pregnancy.

B

FIGURE 160-32. Transverse view of an ectopic pregnancy by TVS. The yolk sac is visible within a gestational sac (black arrow) and outside the uterus (yellow arrows) with an empty endometrium (E). (Photo used with permission from www.aliem.com.)

FREE FLUID IN THE CUL-DE-SAC

A hemoperitoneum is found in approximately 40% to 83% of patients with a complicated ectopic pregnancy. This has a 90% positive predictive value for an ectopic pregnancy. **Anything more than a small amount of pelvic fluid is abnormal. Free fluid in the cul-de-sac and an empty uterus on TVS is an ectopic pregnancy until proven otherwise (Figure 160-33).** The greater the quantity of free fluid in the pelvis, the higher is the likelihood of an ectopic pregnancy. As the amount of pelvic fluid increases, it spreads from the posterior aspect of the cervix to the posterior aspect of the uterus then to above the fundus or around the ovaries. The type of free fluid in the pelvis determines the risk of an ectopic pregnancy. The risk is dependent on the quantity of the free fluid if the free fluid is echo free. **Any amount of echogenic pelvic fluid or complex free fluid represents blood and a high risk for the possibility of an ectopic pregnancy. Hyperechoic masses floating within the echogenic pelvic fluid suggest clotted blood.**

Free fluid in the pelvis occurs frequently with a ruptured ectopic pregnancy. Free fluid may be found with an unruptured ectopic pregnancy. The likelihood of a ruptured ectopic pregnancy increases as the amount of free fluid increases. Clotted blood in the cul-de-sac after a ruptured ectopic pregnancy can distort anatomic landmarks and obscure the US image. Scanning through the hepatorenal space can often lead to identification of an active

hemorrhage. The presence of free fluid in the Morison's pouch of a first-trimester patient with a PUL is highly suggestive of a ruptured ectopic pregnancy.

ASSESSMENT

Perform a complete ED US examination. Classify the US findings into one of three categories: IUP, ectopic pregnancy, or PUL. **Determine the patient disposition based upon their symptoms, the US results, and the β -hCG level.**

Patient disposition is based upon their vital signs, physical examination findings, and bleeding status when the definitive diagnosis of an IUP is made and the patient did not undergo any fertility treatments. If the patient is hemodynamically stable with no significant abdominal tenderness and is not actively bleeding, discuss the risks and symptoms of a spontaneous abortion and instruct the patient to follow-up with an Obstetrician. Consider other causes of abdominal pain (e.g., appendicitis, cholelithiasis, ovarian torsion, and renal colic) if the patient has severe abdominal pain. A complete spontaneous abortion can be managed expectantly with follow-up by an Obstetrician. An incomplete abortion requires an Obstetrician consultation for possible dilatation and curettage. Consult an Obstetrician if there are definite signs of an ectopic pregnancy on the US. The Obstetrician will determine the need for chemical or surgical treatment.

An indeterminate US study demonstrates no signs of an IUP or an ectopic pregnancy and is considered a PUL. Approximately 20% of all ED first-trimester pelvic US examinations are categorized as indeterminate.³² Approximately 20% of patients with an indeterminate US study and β -hCG level > 1000 mIU/mL are found to have an ectopic pregnancy.^{33,34} The possible outcomes with indeterminate first-trimester US studies are early pregnancy, ectopic pregnancy, missed abortion, or incomplete abortion. The patient can be safely discharged with follow-up in 48 hours for reevaluation if they have a PUL and are hemodynamically stable with no significant abdominal or adnexal tenderness, no free fluid on US, and a β -hCG level < 1000 mIU/mL.

AFTERCARE

There is no specific aftercare for the patient based on the US examination itself. All disposition and management decisions are described in the assessment section above. Dispose of the condom or transducer sheath after completing the transvaginal US examination. Soak the endocavity US transducer in an antimicrobial solution. Follow the manufacturer's specifications and the hospital's Infectious Disease Department recommendation for the type of antimicrobial solution to be used and the soak time.

COMPLICATIONS

There are no complications to performing a pelvic US examination during early pregnancy except for mild discomfort during the procedure. US examination of the fetus is generally considered to be safe during pregnancy. Prior studies have reported no association of US with any adverse fetal outcomes. There is a theoretic risk of thermal injury to a fetus with US. Do not perform a Doppler examination in early pregnancy without clinical indications.

SUMMARY

Women with abdominal pain and bleeding during the first trimester of pregnancy are commonly seen in the ED. Pelvic US is the primary imaging modality used in the evaluation of first-trimester symptoms. ED pelvic US has revolutionized the assessment of these patients. The goals of the first-trimester US are to find an IUP and rule out an ectopic pregnancy. Knowledge of sonographic anatomy,

technique, and limitations is essential to perform this procedure. Understanding the principles discussed in this chapter and following a systematic approach to performing a pelvic US examination will maximize the amount of useful information obtained in first-trimester patients.

Uterine Bleeding

Leah W. Antoniewicz, Beth R. Davis, Kara N. Purdy,
Alexis R. Taylor, Lindsay K. Grubish, and
Sarah Christian-Kopp

INTRODUCTION

Uterine bleeding may occur in the absence of current or recent pregnancy, during pregnancy, or in the postpartum period.¹ Abnormal uterine bleeding (AUB) is a term that defines menstrual bleeding that occurs on an abnormal schedule, for an abnormal duration of time, or with an abnormal quantity of blood loss.²⁻⁶ The term dysfunctional uterine bleeding is no longer used.^{7,8} Dysfunctional uterine bleeding is a general term that was used to describe irregular bleeding in the nonpregnant patient. AUB can manifest as heavy menstrual bleeding (HMB). HMB is cyclical or ovulatory bleeding and was previously termed menorrhagia. Intermenstrual bleeding (IMB) refers to bleeding that occurs between menses. This was previously termed metrorrhagia. IMB often has a cervical etiology. Approximately 3% of women have physiologic IMB associated with ovulation.⁹ Approximately 66% of women who have had one or more cesarean births have a defect in the uterus. This is reported as regular postmenstrual spotting.¹⁰ Irregular AUB is caused by ovulatory dysfunction (AUB-O) and is often reported as no cycle for 2 to 3 months. When cycles occur, they are often heavy.

A normal menstrual cycle frequency is 21 to 35 days with a duration of 5 to 7 bleeding days. The International Federation of Gynecology and Obstetrics (FIGO) created the PALM-COEIN classification system in 2011 to help categorize bleeding abnormalities based on the underlying etiology and the bleeding pattern.^{11,12} The acronym divides the causes into structural (PALM) and nonstructural (COEIN). The most common causes of AUB in women of reproductive age include uterine pathology or the "PALM" portion of the classification system.

This chapter will focus on nonpregnant reproductive-age women. Postpartum uterine bleeding or postpartum hemorrhage

is discussed in Chapter 166. Perimenopausal bleeding is generally secondary to hormonal imbalances. Postmenopausal bleeding is a concern for benign etiologies (e.g., fibroids) and malignant etiologies (e.g., cancers). **Postmenopausal bleeding is considered cancer until proven otherwise.** An endometrial biopsy and transvaginal ultrasound (US) should be performed if a uterine source for bleeding is suspected in a postmenopausal woman. Lower genital tract atrophy is the most common benign cause of postmenopausal bleeding and is easily treated with estrogen cream. **All postmenopausal bleeding requires follow-up with a Gynecologist.**

The most important interventions in AUB are to obtain hemostasis and provide volume repletion if needed (e.g., intravenous fluids or blood products). It is essential to determine if the bleeding is occurring in the presence or absence of a pregnancy, the source of the bleeding, and the most appropriate method for hemostasis.

Acute and more conservative management measures (e.g., conjugated equine estrogen, oral contraceptives, medroxyprogesterone acetate, minor surgical interventions, and tranexamic acid) are warranted when uterine bleeding occurs in a stable patient (**Figure 161-1**). Stabilization with more invasive measures is warranted when hypovolemia and hemodynamic instability exist (**Figure 161-1**).

The evaluation and intervention will largely be guided by the patient's hemodynamics and should always start with a pregnancy test. Stable uterine bleeding or continuous bleeding in a stable patient can be comfortably managed as an outpatient. Acute blood loss anemia, hemodynamic instability, massive hemorrhage, and symptomatic anemia warrant urgent Gynecology consultation and intervention. This chapter discusses medical interventions, fluid or blood resuscitation, medication administration, and bedside procedures to slow, stop, or treat the symptoms of acute hemorrhage.

ANATOMY AND PATHOPHYSIOLOGY

The uterus is a highly vascular structure and there are multiple sources of bleeding to consider. The uterus is a unique organ in that some form of bleeding is normal, and therefore, it is sometimes difficult to determine whether a true emergency condition exists. AUB as defined by FIGO is bleeding that is abnormal in duration, frequency, regularity, or volume in the absence of pregnancy.^{12,13} The FIGO approved a new classification system in 2011. They named this using the acronym PALM-COEIN for causes of abnormal uterine bleeding in nonpregnant women of reproductive age. The acronym stands for Polyp, Adenomyosis, Leiomyoma, Malignancy and hyperplasia, Coagulopathy, Ovarian dysfunction, Endometrial etiologies, Iatrogenic etiologies, and Not yet classified.^{7,12,14}

POLYPS (AUB-P)

Polyps are a common and usually benign etiology of AUB. This is especially true in women who are premenopausal or menopausal, although polyps can occur in younger women. Polyps are epithelial growths of the uterine endometrium. They primarily cause IMB. Studies estimate that intrauterine abnormalities account for almost 50% of patients presenting with AUB.¹¹ Endometrial polyps are one of the common causes of AUB in premenopausal and postmenopausal patients. Polyps are derived from hyperplastic overgrowth of endometrial glands and stroma usually from estrogen stimulation. Some risk factors for polyp formation include hormone replacement therapy, obesity, tamoxifen therapy, and unopposed estrogen therapy.

Common presenting symptoms include IMB, postcoital bleeding if the polyp is prolapsed, and postmenopausal bleeding. Polyp-related symptoms may be controlled with medical therapy in the

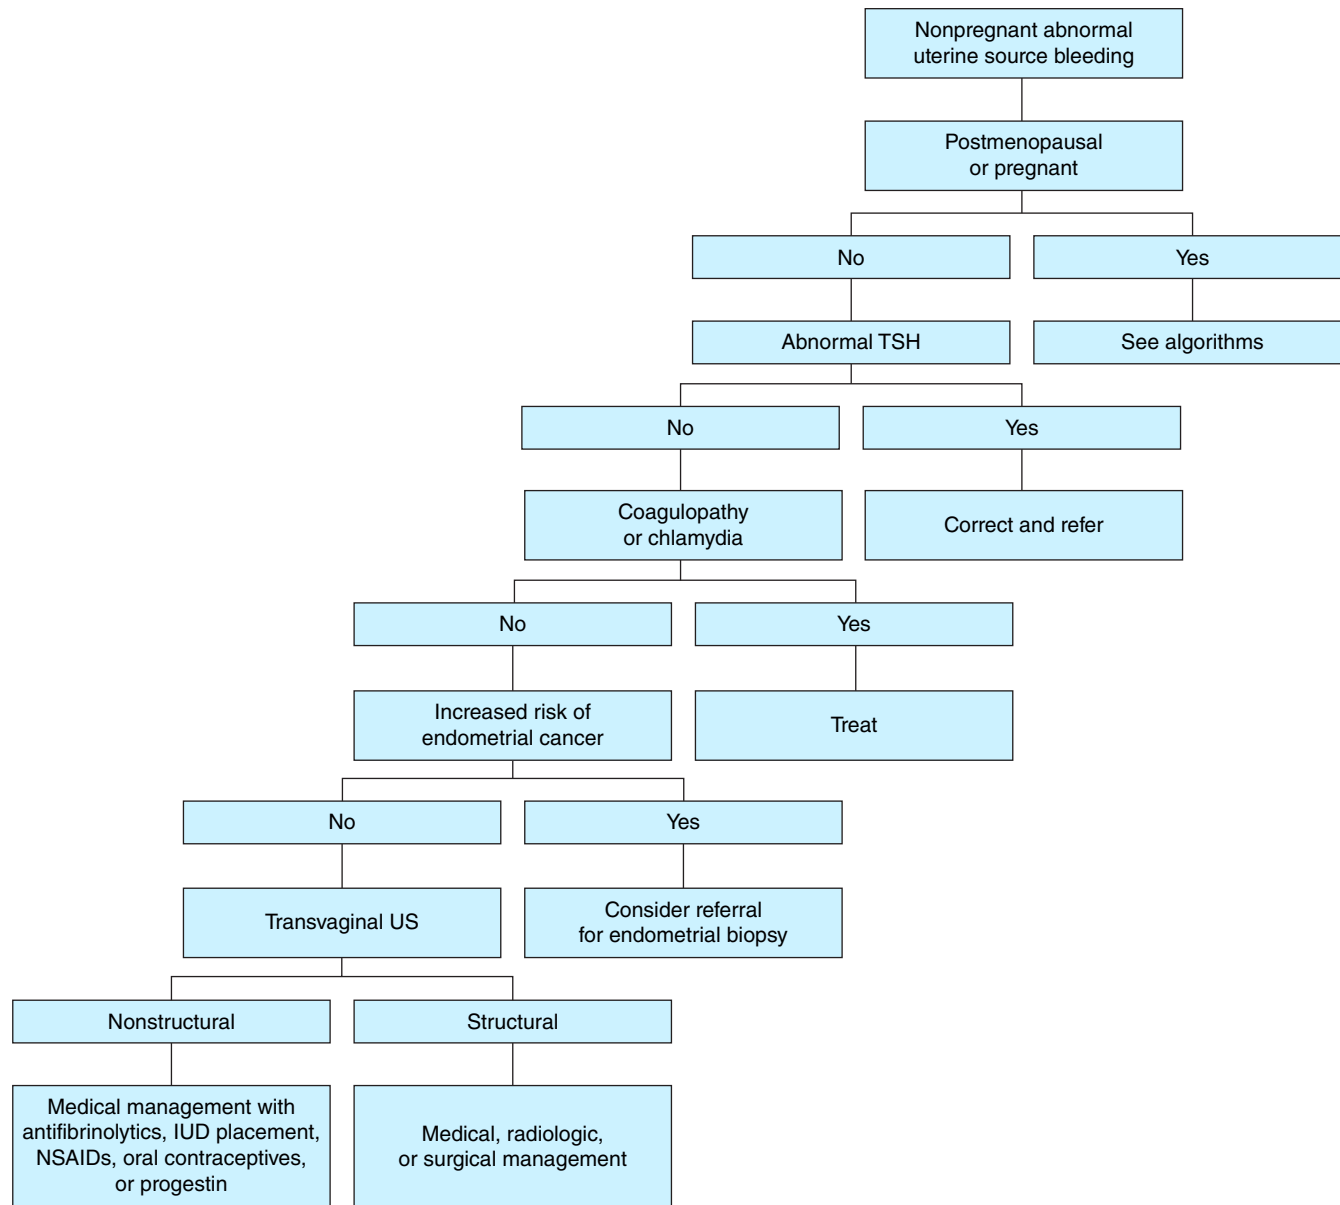

FIGURE 161-1. Algorithm for the management of AUB.

short-term. Transvaginal US may assist in the diagnosis if a thickened or heterogeneous endometrial stripe is noted. Referral to a Gynecologist for outpatient management is appropriate if there is concern for an underlying structural cause in the stable patient. Sonohysterogram or hysteroscopy is the preferred imaging for suspected polyps. Definitive diagnosis is with histologic examination via endometrial biopsy or polypectomy. Definitive management is with hysteroscopic polypectomy.

ADENOMYOSIS (AUB-A)

Adenomyosis occurs when there is ectopic endometrial glands and stroma within the myometrium. The ectopic tissue is stimulated by endogenous hormones that induce hypertrophy of the myometrial tissue. This often results in a “globular” appearance radiographically and a palpable boggy texture of the uterus. The uterus may remain a normal size in some patients but adenomyomas, which appear and act like leiomyomas, may develop.

AUB and dysmenorrhea are the most common presenting symptoms that may worsen with age. Clinical symptoms and physical

examination typically raise suspicion for adenomyosis. Transvaginal US and magnetic resonance imaging (MRI) may assist in the diagnosis with findings of asymmetric myometrium, myometrial cysts, and increased heterogeneity. Definitive diagnosis requires pathologic confirmation after hysterectomy. Medical management of symptoms is similar to that of leiomyomas (i.e., gonadotropin-releasing hormone [GnRH] analogues, nonsteroidal anti-inflammatory drugs [NSAIDs] for pain, and oral contraceptives). Definitive treatment is with a hysterectomy.

LEIOMYOMA (AUB-L)

Leiomyomas (i.e., fibroids) are benign tumors of muscle cell origin and are the most commonly occurring pelvic tumor.¹⁵ Leiomyoma presents in nearly 70% of Caucasian women and 80% of African American women by age 50.¹⁶ These numbers increase with age but decrease with menopause.¹⁷ Leiomyomas are likely related to a combination of hormones and genetic factors, although the exact cause is unknown. Up to 30% of women with leiomyomas will have AUB and pelvic pain or pressure. Large leiomyomas may be palpable on examination.

Leiomyomas may be in multiple locations including intramural, pedunculated, submucosal, or subserosal. Symptoms typically vary based on size and location of the leiomyomas. Subserosal and pedunculated leiomyomas typically cause bulk symptoms (e.g., pelvic pain and pressure) whereas intramural and submucosal leiomyomas cause heavy menstruation. Patients who are asymptomatic do not require any intervention. Medical treatments for leiomyomas include medications (e.g., antifibrinolytic agents, aromatase inhibitors (currently experimental), GnRH agonists, and oral contraceptives).^{15,18}

Oral contraceptives are typically the first-line treatment for AUB-L. Both combined and progesterone-only contraceptive pills have been shown to decrease bleeding secondary to leiomyomas without stimulating growth of the leiomyomas. The levonorgestrel intrauterine device (IUD; e.g., Mirena) has been effective in reducing the bleeding and cramping associated with leiomyomas and adenomyosis. There may be a higher risk of IUD expulsion depending on the location of the leiomyomas.

Leuprolide acetate (i.e., Lupron) is a GnRH agonist approved by the U.S. Food and Drug Administration (FDA) that can be used for the management of leiomyomas. Lupron effectively induces a menopausal state resulting in amenorrhea in most patients and a decrease in leiomyoma volume within 3 months of treatment.¹⁶ Leuprolide acetate therapy is temporary because of long-term side effects from estrogen deprivation. Prescribe daily add-back therapy with 5 mg of norethindrone acetate to reduce side effects. Lupron is typically used to correct underlying anemia and shrink leiomyoma size in anticipation of a surgical intervention.

There are procedures that may be performed for symptomatic management with uterine preservation. One option that is becoming more readily available is uterine artery embolization (UAE) where an Interventional Radiologist uses gelatin microspheres to embolize the uterine artery via cannulation of the femoral artery. The resulting vascular occlusion results in a decrease of bulk symptoms.¹⁶ The rates of complications are typically lower than those associated with surgical interventions and postprocedure recovery is faster. This treatment is not recommended for patients who desire future fertility.

MRI-guided focused US surgery (MRgFUS) is a noninvasive approach to managing leiomyomas. It uses high-intensity US waves directed into a leiomyoma that was localized with MRI. The US waves are focused to small areas of the leiomyoma to raise the temperature and cause cellular death. A water bath is used between the skin and the US transducer to maximize acoustic contact. The benefits of MRgFUS include an alternative to hormonal therapy, an alternative to surgery, few side effects, outpatient basis that does not require staying in the hospital, preservation of future fertility, relative noninvasiveness, treatment in approximately 3 hours, and return to work in a few days. Contraindications include extensive abdominal skin scarring, implanted devices (e.g., neurostimulators and pacemakers), inability to lie still for 3 hours, pregnancy, and poor health. This procedure is not available at all facilities. Long-term data regarding efficacy are currently lacking.

Endometrial ablation may be an option for some patients who desire uterine preservation depending on the size and location of leiomyomas. Ablation involves use of energy (e.g., microwave, radio-frequency, or thermal) to destruct the uterine lining. The procedure is typically done in the Operating Room although office procedures are becoming more common. **Patients need to have completed childbearing and the possibility of cancer needs to be excluded before considering an ablation procedure.** A decrease in menstrual flow is the most common outcome of endometrial ablation while many patients achieve amenorrhea.

Myomectomy, or removal of the leiomyoma, is an alternative to hysterectomy that preserves fertility in patients who desire future

childbearing. There are various approaches to myomectomy and the mode depends on the location of leiomyomas, size of leiomyomas, and the skill level of the Gynecologist. An abdominal (i.e., laparotomy or mini-laparotomy) or laparoscopic approach is appropriate for subserosal or intramural leiomyomas whereas a hysteroscopic approach is used for submucosal leiomyomas. Myomectomy carries risks associated with the surgical procedure and the risk of recurrence of leiomyoma growth which is higher if there are multiple leiomyomas present. Hysterectomy is the definitive treatment for leiomyomas and may be used if medical management fails. Hysterectomy may be accomplished via various routes (e.g., abdominal, laparoscopic [single-site, robotic-assisted], or vaginal). The approach to hysterectomy will depend on Gynecologist skill, patient risk factors, uterine mobility, and uterine size.

MALIGNANCY AND HYPERPLASIA (AUB-M)

Endometrial hyperplasia and malignancy is the most concerning cause of AUB. This should be considered in any female with AUB who is menopausal or postmenopausal or who is younger with risk factors for genital tract malignancy.¹⁹⁻²¹ Risk factors for endometrial hyperplasia and malignancy include estrogen-secreting tumors, increasing age, Lynch syndrome, obesity, nulliparity, and unopposed estrogen (e.g., anovulatory cycles, hormone replacement therapy, and tamoxifen therapy). Initial evaluation should include a thorough history and physical examination. Pelvic US may be useful for evaluation, particularly for measurement of the endometrial stripe in postmenopausal patients. Definitive diagnosis requires endometrial sampling with an office endometrial biopsy or a hysteroscopy with dilation and curettage in the Operating Room.

Treatment for hyperplasia may be conservative if the patient desires preservation of fertility and typically involves progesterone therapy. Definitive treatment for hyperplasia or malignancy is achieved with a hysterectomy. **Arrange a prompt outpatient referral of stable patients with a possibility of endometrial hyperplasia or malignancy to a Gynecologist or Gynecologic Oncologist for an endometrial biopsy.**

COAGULOPATHY (AUB-C)

Bleeding disorders are common causes of AUB, especially in adolescents.^{22,23} von Willebrand disease is the most common cause. However, any acquired coagulopathy (e.g., thrombocytopenia from cirrhosis), autoimmune disorder, coagulopathy, or myeloproliferative disorder can be the cause. Family and patient history of bleeding disorders, easy bruising, hemarthrosis, menorrhagia, or other symptoms suggesting coagulopathy are an integral portion of the work-up.

Approximately 20% of women presenting with HMB have an underlying bleeding disorder.²⁴ All adolescents with HMB and all adults with a coagulopathy-positive screen (Table 161-1) should

TABLE 161-1 Coagulopathy Screening for Underlying Bleeding Disorders⁹

Heavy menstrual bleeding since menarche and 1 of the following:

- Postpartum hemorrhage
- Surgery-related bleeding
- Dental work-related bleeding

Or 2 or more of the following:

- Bruising 1–2 times per month
- Epistaxis 1–2 times per month
- Frequent gum bleeding
- Family history of bleeding symptoms

have a complete blood count (CBC), partial thromboplastin time (PTT), and prothrombin time (PT). Specific tests for other coagulopathies (e.g., factor VII deficiency, von Willebrand factor antigen, and von Willebrand-ristocetin cofactor activity) may be indicated depending on the history and initial laboratory testing.¹¹ AUB-C includes those patients on anticoagulants because the management is similar to inherited disorders.

OVARIAN DYSFUNCTION (AUB-O)

Although most AUB occurs during ovulatory cycles, anovulation is the most common cause of nonstructural bleeding. This can lead to anemia and diminished quality of life. Normally the endometrium is exposed to estrogen during the development of the ovarian follicle then both estrogen and progesterone after ovulation. Normal bleeding occurs after these hormones are withdrawn. The endometrium is exposed to unopposed estrogen if ovulation does not occur that can cause abnormal bleeding. This can be physiologic or pathologic. Physiologic causes include adolescence, lactation, menopause, and perimenopause. Pathologic causes include hyperandrogenic anovulation (e.g., polycystic ovarian syndrome, congenital adrenal hyperplasia, androgen-secreting tumors), hyperprolactinemia, hypothalamic dysfunction (e.g., anorexia, exercise, or stress), iatrogenic (e.g., chemotherapy or radiation), medications, pituitary disease, premature ovarian failure, or thyroid disease.²⁵

Ovarian dysfunction has many potential causes and can affect any age group.⁸ It usually occurs during perimenarche in adolescent females and is often due to an immature hormonal axis. Ovarian dysfunction in this age group produces minimal bleeding in most cases. Heavy bleeding is a concern for a coagulopathy. Follicular degradation and hormonal fluctuations are the primary causes of anovulatory bleeding in the perimenopausal woman. Hypothyroidism may be associated with ovarian dysfunction outside of these age groups. Other medical causes of ovarian dysfunction and AUB-O include adrenal disorders, eating disorders, exogenous hormones, hormonal disorders, intense exercise, or steroid use.

Structural and endometrial pathology must be ruled out before a diagnosis of AUB-O can be made. Cycles that vary in length by more than 10 days are likely anovulatory. Anovulatory cycles are common for the first 3 years after menarche in the adolescent patient (i.e., 13 to 18 years). Examine adolescent women for a coagulopathy, pregnancy, sexually transmitted diseases, and sexual trauma. Women age 19 to 39 most commonly have polycystic ovarian system whereas those over age 40 most commonly have AUB-O due to the menopausal transition. **All women 45 and older who have suspected AUB-O must have an endometrial biopsy because of the increased risk of cancer. Refer patients with prolonged anovulatory bleeding or other risk factors for increased estrogen exposure (e.g., obesity) for an endometrial biopsy.** Laboratory testing of suspected AUB-O patients includes a pregnancy test, prolactin level, and thyroid-stimulating hormone (TSH). Refer the patient to a Gynecologist for an endometrial biopsy or sonohysterography.

Treatment is aimed at the underlying endocrine disorder which includes exogenous steroid use. This can be progesterone alone or combined estrogen and progesterone. Use progesterone only if contraindications to estrogen exist (e.g., coagulopathies, hypertension, or smokers over 35 years of age). Otherwise, combined contraceptives are a better choice because they not only protect the patient from unwanted pregnancy but also allow for predictable bleeding. Combined contraceptives can be used in an extended fashion (i.e., skipping the placebo week) to help recover from anemia. Estrogen will decrease menopausal symptoms for women in the menopause transition and maximize bone density. See **Table 161-2** for a list of therapies. Weight loss and exercise may be prescribed in overweight women. Failing medical therapy requires further investigation by a

TABLE 161-2 Hormonal Therapy for AUB-O

Progesterone only	Combined estrogen and progesterone
Medroxyprogesterone acetate 10–20 mg (Provera)	Oral contraceptive pill
Norethindrone 10 mg	Transdermal patch
Megestrol acetate 40 mg (Megace)	Vaginal ring
Depot medroxyprogesterone (Depo-Provera)	Oral contraceptive taper for stable active bleeding and anemia
Levonorgestrel intrauterine device (IUD) (Mirena)	IV estrogen for unstable active bleeding and anemia

Gynecologist and includes endometrial biopsy, hysteroscopy, imaging, or uterine ablation.

ENDOMETRIAL CAUSES (AUB-E)

AUB sometimes occurs in the setting of a normal ovulatory cycle, normal uterine tissue, and no other medical cause. Menstruation is often heavy in these situations. This is due to abnormal prostaglandin synthesis and receptor upregulation, increased local fibrinolytic activity, and increased tissue plasminogen activator activity.¹¹ It is often treated with oral contraceptives and NSAIDs for symptomatic treatment of pain. Other treatment includes tranexamic acid or levonorgestrel-releasing IUDs. More intensive treatments of hysterectomy and uterine ablation may be considered by the Gynecologist in severe cases.

Inflammation and infection can cause IMB. Acute endometritis is seen in the settings of pelvic inflammatory disease, postabortion, postpartum hemorrhage, and after procedures. Refer to the current Centers for Disease Control and Prevention recommendations for inpatient and outpatient treatment.

IATROGENIC CAUSES (AUB-I)

Medications are common causes of AUB (**Table 161-3**). Many antipsychotics cause hyperprolactinemia by blocking dopamine receptors. Oral contraceptives and other gonadal steroid medications can cause unscheduled or “breakthrough bleeding.” This is more common with initiation of the hormones or prolonged use. IUDs can cause both HMB and IMB. The levonorgestrel-releasing IUD can cause HMB or IMB that usually resolves with time. It can eventually cause amenorrhea. The copper IUD often causes HMB that can be treated with perimenstrual NSAIDs. It may be easy to attribute AUB to these common medications. Do not rule out other potential causes of AUB without a thorough evaluation and Gynecologist referral.

TABLE 161-3 Medications and Medical Devices That Can Cause AUB

Antiemetics, especially metoclopramide
Antihypertensives, especially methyldopa and verapamil
Antipsychotics, especially first generation
Contraceptive rings
Douches
Exogenous hormones
Glucocorticoids
Hormone replacement therapy
Intrauterine devices
Medications that affect the hepatic P450 system
Medications that affect the hormonal axis
Oral contraceptives
Pessaries
Tricyclic antidepressants, especially clomipramine
Vaginal irritants

OTHER CAUSES (NOT YET DETERMINED) (AUB-N)

Intravaginal devices (e.g., pessaries or hormonal contraceptive rings), douching, or other irritants may cause vaginitis and bleeding. Sexually transmitted infections, sexual trauma, and vaginal infections are a common cause of AUB, especially in younger sexually active women. Other causes include arteriovenous malformations (AVMs), chronic endometritis, and etiologies that do not fit into the other categories. Bleeding from an AVM will often present as excessive bleeding after a uterine procedure (e.g., dilation and curettage).^{26,27}

HISTORY AND PHYSICAL EXAMINATION

The patient's history and physical examination may steer the Emergency Physician toward a cause. Determining the exact cause of a patient's AUB is not the goal for the Emergency Physician. The work-up done by the Emergency Physician will likely be an integral part of a consultant's evaluation of the patient.

Important aspects of the history include the last Pap smear and its results, familial bleeding problems or disorders, patient bleeding problems or disorders, uterine pathology, cancer history, and recently starting or stopping medications. Key points to obtain from the medical history include a thorough menstrual history (e.g., onset of menarche, typical cycle frequency, days of bleeding, clots, number of pads/tampons used, and presence or absence of pain with cycles) and screening for an underlying bleeding disorder. Family history should focus on any bleeding or clotting disorders. Review any medications and include any herbal supplements. Inquire what treatments have controlled bleeding in the past. Women with HMB tend to be anemic, change sanitary products at night, change sanitary products at < 3 hour intervals, pass clots > 1 inch in diameter, and use > 21 sanitary products in a cycle.²⁸

The physical examination can help determine the source of bleeding (e.g., cervical, rectal, urethral, uterine, vaginal, or vulvar). The examination includes a speculum examination to evaluate for abnormalities (e.g., cervical or vaginal) and a bimanual examination (e.g., consistency, mobility, shape, size, and tenderness) of the pelvic organs. A fibroid uterus may feel enlarged with an irregular contour. A uterus with adenomyosis may feel slightly enlarged, globular, and boggy (i.e., soft).

Corporeal signs are helpful in diagnosis. Extremes of weight cause hypothalamic dysfunction. Hirsutism and acne are signs of increased androgen production that can be seen with congenital adrenal hyperplasia and polycystic ovarian syndrome. Acanthosis nigricans is a sign of insulin resistance and is also seen in polycystic ovarian syndrome. Exophthalmos, lid lag, and myxedema are signs of thyroid dysfunction. Petechiae, ecchymosis, skin pallor, and swollen joints may be indicative of a bleeding disorder.

The initial laboratory evaluation should include a pregnancy test, CBC, and TSH. Perform chlamydia testing, coagulation studies (e.g., international normalized ratio [INR], PT, and PTT), iron studies, and a type and screen if indicated. Pelvic US is the first-line imaging to assess for structural causes of AUB (e.g., adenomyosis or leiomyomas). Refer the patient to a Gynecologist for sonohysterography or diagnostic hysteroscopy if an intrauterine polyp or submucosal leiomyoma is suspected on initial imaging. Both methods use fluid to distend the endometrial cavity which allows visualization of protruding structures.

EQUIPMENT

- Speculum, various sizes
- Water-soluble lubricant
- Balloon catheters to tamponade the uterus

- Cardiac monitor
- Pulse oximeter
- Noninvasive blood pressure monitor
- Oxygen source
- Nasal cannula and face masks
- IV access supplies (Chapters 59, 61 to 64, and 70)
- Resuscitation equipment
- US machine
- US transducers
- US transducer cover
- US gel

At least two transducers are required to obtain a good US examination (Chapter 160). Perform an abdominal US with a 3.0 to 5.0 MHz curvilinear transducer. The lower frequency of this transducer allows imaging of the pelvic organs through the abdominal wall. Perform the intravaginal US with a 8.0 to 13.0 MHz endocavitary transducer. This high-frequency and long-shaped transducer provides a wide field of view and details of the pelvic organs.

PATIENT PREPARATION

Explain the risks, benefits, and alternative procedures to the patient and/or their representative. Obtain an informed consent for the procedure and place this in the medical record. Place the patient on the cardiac monitor, noninvasive blood pressure cuff, pulse oximetry, and supplemental oxygen to monitor them during and after the procedure. Obtain IV access. Resuscitate the patient with fluids and blood products as necessary. Have resuscitation medications at the bedside if needed. Don personal protective equipment to protect from contact with the patient's blood and body fluids.

Prepare the US transducer if using US (Chapter 160). Apply US gel over the footprint of the transducer. Place the gel-coated US transducer in the sterile cover. Place US gel on the transducer. Place the patient supine. Explain the transabdominal and transvaginal US examination.

Perform a transabdominal US examination. This should be performed first to scan the pelvis in the transverse and sagittal planes (Chapter 160). Place the transducer in the midline and just below the pubic symphysis. Make sure the marker is facing cephalad. The filled bladder is a sonographic window when scanning the pelvis. Do not wait until the bladder fills if not filled with fluid. Find the bladder and vaginal stripe as landmarks. The bladder is fluid filled with a black anechoic center. The vaginal stripe is a bright white line. The uterus is posterior to the bladder. Follow the vaginal stripe upward into the cervix and uterus. Scan with the transducer sagittally in the left and right of midline to look for normal anatomy and pathology. Turn the transducer 90°. Scan with the transducer transversely up and down to look for normal and pathology.

Perform an endovaginal US (Chapter 160). Ask the patient to empty their bladder or catheterize the bladder (Chapter 173). Place the patient supine with their legs abducted and knees bent 45° or the frog-leg position. Carefully insert the endocavitary transducer. Scan the pelvic organs sagittally and transversely (Chapter 160).

TECHNIQUES

MEDICAL MANAGEMENT

Management of acute AUB depends on clinical stability and the suspected etiology.^{5,29-32} First-line therapies for stable bleeding include gonadal steroids (more effective) and NSAIDs (less effective).

NSAIDs block the formation of prostacyclin, a thromboxane antagonist, and decrease uterine blood flow. Steroid hormone treatment includes progesterone alone (less effective) and combined estrogen and progesterone oral contraceptives (more effective). Combined oral contraceptives containing 35 mcg of estrogen may be used in multidose regimens or pill tapers. One dosing regimen includes taking a combined oral contraceptive three times a day for 7 days. An example of a pill taper is one pill three times a day for 3 days, one pill twice a day for 3 days, then one pill daily to finish the pack. Skip the placebo pills and start a new pack to prevent bleeding. Consider prescribing an antiemetic for possible nausea and vomiting.

Contraindications to combined oral contraceptives include heavy cigarette smoking in a patient older than 35 years, history of venous or arterial thromboembolism, hypertension, migraine with aura, past or present breast cancer, prolonged immobilization, severe liver disease, or valvular heart disease. See U.S. medical eligibility criteria for contraceptive use (www.cdc.gov/reproductivehealth/unintendedpregnancy/usmec.htm).

Medroxyprogesterone acetate (Provera) is a progesterone-only alternative to help with acute AUB in patients who have contraindications to estrogen. This synthetic progestin has an antimitotic effect and allows the endometrium to atrophy. A regimen that has shown to be effective in decreasing bleeding is oral Provera 20 mg three times a day for 7 days followed by 10 mg daily for maintenance. Megestrol acetate (Megace) is another progesterone agent that may be used for acute AUB in doses as high as 80 mg twice a day until the patient can be seen by a Gynecologist. Contraindications to progesterone therapy include active liver disease, active venous thromboembolism, and breast cancer.

Tranexamic acid (Lysteda) is a synthetic analogue of the amino acid lysine. It is an antifibrinolytic agent that works by displacing plasmin from fibrin. Both intravenous (IV) and oral forms are available for use.^{31,33} Oral tranexamic acid can be used for outpatient treatment of uterine bleeding in a hemodynamically stable patient. Consider IV tranexamic acid for uterine bleeding in a hemodynamically unstable patient. However, massive uterine bleeding is an off-label use. Oral tranexamic acid is an alternative to hormone therapy for the management of AUB at a dose of 1300 mg every 8 hours for 5 days. An alternative is 300 to 1000 mg orally three times a day for 3 days. Administer 1 gm IV over 10 minutes and an additional 1 gm 8 hours later for HMB. This therapy has been highly effective at treating chronic AUB with a reduction in bleeding of nearly 50% but currently has limited data for use in acute AUB.¹⁰ **Use tranexamic acid with caution in patients at high risk for thrombosis.**

IV conjugated equine estrogen or Premarin (25 mg every 4 to 6 hours for 24 hours) has been shown to successfully stop bleeding in approximately 75% of patients within 8 hours of initiation for unstable bleeding or severe anemia.¹³ Contraindications to IV estrogen therapy include breast cancer, history of venous or arterial thrombosis, or active liver disease.

Other medical treatments include GnRH analogues or levonorgestrel-releasing IUD systems.³⁴ GnRH analogues downregulate pituitary receptors and suppress GnRH release. It is a form of medical castration. Prolonged treatment with GnRH analogues is associated with osteoporosis and postmenopausal symptoms. These medications should be administered and managed by a Gynecologist.

INTRAUTERINE BALLOON PLACEMENT

Another option for stabilization is uterine tamponade.^{21,35-45} This can be used in conjunction with medical therapies. There are various methods that provide intrauterine compression including 4 inch gauze packing with the tail extending through the cervix and balloon catheters. The uterine packing or balloon can remain in place for 24 hours while the patient is resuscitated with fluids and blood products. Antibiotic prophylaxis with a cephalosporin is recommended after uterine packing.

There are multiple balloon catheters that may be used for uterine tamponade including Foley catheters (Chapter 173), Bakri (Figure 161-2A) or Ebb balloons (Figure 161-2B), Sengstaken-Blakemore balloons (Chapter 81), Rusch catheters (Figure 161-2C), and condom catheters. The Bakri tamponade balloon catheter and

A

B

C

FIGURE 161-2. Balloon catheters. A. Bakri. B. Ebb. C. Rusch.

the Ebb complete tamponade system are large-volume balloon catheters specifically designed for placement in the uterus for control of uterine hemorrhage. The Rusch urologic balloon is a large-volume urinary catheter originally developed with the intent to control vesicular hemorrhage. All three devices can be used to treat uterine bleeding as a tamponade system. The pressure applied by the inflated balloon against the uterine wall causes hemostasis. Balloon catheters, except Rusch and condom catheters, have an outflow component that allows for continued measuring of blood loss and monitoring of hemostasis. The balloons typically remain in place for 12 to 24 hours with antibiotic prophylaxis while hemodynamic stability is achieved. The balloons may accommodate up to 500 mL of saline except Foley catheters. Multiple Foley catheters may be tied together and inflated with 30 to 60 mL each. Dilation and curettage may be necessary for definitive care.

■ INDICATIONS

Placement of an intrauterine balloon catheter may be successful in stopping uterine hemorrhage and result in hemostasis. **It is a temporary measure while awaiting more definitive surgical procedures (e.g., arterial embolization, arterial ligation, or hysterectomy).** An intrauterine balloon can be used for suspected AUB when ectopic pregnancy and urogenital tract lacerations have been ruled out. The use of a balloon is indicated before more invasive surgical approaches. It is also placed for postpartum hemorrhage.

■ CONTRAINDICATIONS

Known infection (i.e., vagina, cervix, or uterus) and uterine abnormalities are a contraindication to balloon placement. The patient can become more septic when the balloon is inflated and the infection leaves the female genital tract. Balloon inflation would be unlikely to apply effective tamponade for hemorrhaging uterine cancer and uterine rupture. Intrauterine balloon placement is contraindicated when the source of bleeding is suspected to be extra-uterine (e.g., vaginal or vulvar injuries leading to bleeding distal to the uterus or in ectopic pregnancy). Avoid intrauterine balloons if the patient has any known allergies to device materials. Arterial bleeding requiring surgical exploration or angiographic embolization is a contraindication to inserting a balloon. Disseminated intravascular coagulation and other coagulopathies are a relative contraindication. Surgery of the uterus prohibits device inflation and bleeding tamponade.

■ EQUIPMENT

- Internal antiseptic solution (e.g., povidone iodine)
- 60 mL syringe
- Balloon catheter device
- IV extension tubing with attached bag spike
- 500 mL sterile liquid (e.g., saline or water)
- Iodine gauze or antibiotic-soaked gauze
- Ring forceps

The Bakri balloon catheter is a common device that is for one-time use. It is made of silicone and contains no latex. A large-bore drainage channel is rarely blocked by blood clots. The balloon contains up to 500 mL of fluid. The catheter measures 43.5 cm in length and is a size 24 French (i.e., 8 mm).

■ PATIENT PREPARATION

Consider premedicating the patient with pain and/or nausea medications. Intrauterine balloon tamponade can cause significant pain. Determine the uterine volume by either direct examination or US measurements. This prevents balloon overdistension and rupture

FIGURE 161-3. Transvaginal placement of a balloon catheter into the uterus.

of the uterus. Evaluate the genital tract for lacerations or trauma. Clear the uterus of placental fragments if the patient is postpartum. Clean the vulva, vagina, and cervix with povidone iodine or other internal body safe solution. Place a Foley catheter into the bladder to monitor urine output.

■ TECHNIQUE

Place the patient in the lithotomy position. The description is for the Bakri balloon. Another balloon catheter can be used and inflated within the uterus. Carefully and gently grasp the cervix with a ring forceps to stabilize its position. Carefully and gently insert the balloon portion of the catheter fully through the vagina and cervical canal and past the internal ostium and into the uterus (**Figure 161-3**). Use US guidance if possible during the insertion. Pull the catheter until the base of the balloon is at the internal cervical ostium (**Figure 161-4**).

Attach the IV extension tubing connected to the sterile fluid to the stopcock. Attach the 60 mL syringe to the stopcock. Slowly inflate the balloon with sterile liquid (e.g., Ringer's lactate, saline, or water) to a maximum of 500 mL (**Figure 161-4**). **Do not inject the balloon with air or any gas. Do not overinflate the balloon and cause a uterine rupture.** Consider placing the sterile liquid in a separate container when measured to ensure proper volume instillation to avoid losing count of the syringes used. Confirm that the balloon is properly placed using transabdominal US.

Apply light tension to seat balloon against the internal ostium of the cervix. Secure the catheter to the patient's thigh or hang a weight from the catheter. **Do not exceed 500 gm of tension weights.** This tension is essential for tamponade of bleeding vessels. Consider packing the vagina to apply counter pressure and tamponade

FIGURE 161-4. Placement and inflation of a balloon catheter. **A.** Improper placement. **B.** Proper placement.

FIGURE 161-5. Transabdominal placement of a balloon catheter into the uterus.

the bleeding. Use iodine gauze or antibiotic-soaked gauze for the vaginal packing. Connect the drainage port to a collection bag to monitor any continued bleeding. Flush the drainage port and tubing periodically with sterile saline to remove any clots.

An alternative technique is used by the Gynecologist if placing the balloon catheter through an abdominal incision (e.g., after cesarean section) (**Figure 161-5**). Insert the inflation port through the skin incision and into the uterus. Thread the proximal end of the catheter through the internal ostium from within the uterus to properly seat the balloon within the uterine cavity. Close the uterus and skin in the usual fashion with care to avoid puncturing the balloon and/or catheter.

■ BALLOON REMOVAL

Removal of the catheter is simple. Relieve the tension on the catheter by removing any weights and detaching the catheter from the patient's thigh. Attach a 60 mL syringe to the balloon inflation port. Completely deflate the balloon in increments to allow patient observation throughout the removal procedure. Remove any vaginal packing, if present. Gently remove the catheter. Inspect the balloon to assess for damage or possible retained balloon fragments. Discard the balloon catheter. Monitor patient for signs of bleeding.

■ COMPLICATIONS

The catheter and balloon may be inappropriately placed. The balloon can be overinflated and risk uterine rupture. Underinflation of the balloon will result in lack of tamponade and continued bleeding. Bleeding can persist around the balloon. Insufficient tension on the catheter may not provide effective tamponade.

■ SUMMARY

Place the Bakri balloon for non-life-threatening uterine bleeding. The balloon must be completely within the uterus, inflated to a maximum of 500 mL, and placed under tension to provide a source for tamponade. Remove the balloon within 24 hours. Closely monitor patients requiring uterine balloon placement for signs of continued hemorrhage.

REFERRAL TO A GYNECOLOGIST

Some patients require a Gynecologist consult in the Emergency Department. Heavy uterine bleeding may require uterine ablation. Symptomatic leiomyomas may require a myomectomy. Long-term bleeding, bleeding resulting in acute blood loss anemia, or hemodynamic instability may require a hysterectomy.

ASSESSMENT

The balloon and/or packing can be left in place for up to 24 hours. Resuscitate the patient with fluids and blood products as necessary. Frequently reassess the patient for continued bleeding and hemodynamic stability. Monitor any continued hemorrhage from the vagina. Consult a Gynecologist if bleeding stops and the patient is stable. Emergently consult a Gynecologist for continued bleeding. The continuously bleeding patient must be taken to Invasive Radiology or the Operating Room to stop the bleeding.⁴⁶

AFTERCARE

Stable patients with minimal bleeding and minimal symptoms can be discharged from the Emergency Department with Gynecology follow-up in 24 to 48 hours. Prescribe oral iron and multivitamins. NSAIDs will help manage minor bleeding and pain. These patients may receive elective dilation and curettage, endometrial ablation, and outpatient hormonal therapy.

Severe bleeding requires multiple interventions after placement of the balloon catheter to tamponade uterine bleeding. Reverse any bleeding disorders. Consider administering fresh frozen plasma and 10 mg of vitamin K IV to patients taking warfarin (Coumadin), patients with end-stage renal disease, or patients with a high INR. Consider administering 0.4 mcg/kg desmopressin IV over 10 minutes if the patient has a platelet disorder or renal disease. Administer IV estrogen if not contraindicated. Consult a Gynecologist. Do not reinflate the balloon and do not reinsert the balloon if bleeding recurs during deflation or removal. Use a new balloon catheter. Continual bleeding or recurrent bleeding requires more invasive treatments in the Operating Room or Invasive Radiology.⁴⁶

COMPLICATIONS

The indications and contraindications to some medications have already been discussed. The catheter and balloon may be inappropriately placed. The balloon can be overinflated and risk uterine rupture. Underinflation of the balloon will result in lack of tamponade and continued bleeding. Bleeding can persist around the balloon. Insufficient tension on the catheter may not provide effective tamponade. Insertion and inflation of a balloon catheter in an infected uterus can result in sepsis. Uterine abnormalities can result in difficult balloon inflation, difficult insertion, rupture, and traumatic lacerations. Continued bleeding can result from balloon ineffectiveness, hemorrhage from cancer necrosis, extrauterine bleeding, and uterine rupture. Only inflate the balloon with liquid to prevent a gas embolism.

Complications can arise from placing a Foley catheter (Chapter 173). The catheter can allow bacteria into the bladder and cause a fever, bladder infection, hematuria, and a kidney infection. This can partially be prevented by using strict sterile technique.

SUMMARY

Abnormal uterine bleeding is a very common complaint in the Emergency Department. Nonpregnant uterine bleeding can be due to many causes and result in rapid large-volume blood loss. Most AUB has a structural cause. Rule out coagulopathy, endocrinopathy, malignancy, and pregnancy. Bleeding is often due to ovulatory dysfunction if a structural cause is not found and can be medically treated in most cases. Any suspicion of cancer requires a Gynecologist referral and possible biopsy. Consult a Gynecologist immediately if a patient is actively bleeding and is hemodynamically unstable. Medical therapies include tranexamic acid and blood product transfusion while awaiting Gynecology consultation.

Administer hormonal therapies for lower volume bleeding. Numerous procedures are available for bleeding (e.g., balloon catheter placement, myomectomy, and uterine ablation).

Normal Spontaneous Vaginal Delivery

Stephen Dunay and Simeon Ashworth

INTRODUCTION

Emergency Physicians must be prepared to manage the precipitous delivery of a newborn. It is a rare occurrence and requires a good amount of preparation. The Emergency Department is not the ideal environment in which to deliver a newborn.¹ A Labor and Delivery suite with a specialist trained in handling potential complications (e.g., malpresentation, prematurity, or prolapsed cord) is preferred. The Emergency Physician will need to deliver the infant when transfer to a facility with a trained Obstetrician, Family Physician,

or Certified Nurse Midwife is not feasible.² A thorough understanding of the physiology of pregnancy and labor, the evaluation of the pregnant female, and the proper technique of delivery will help to ensure the safety of both mother and fetus.

Labor involves the repetitive uterine contractions that lead to cervical changes (i.e., dilation and effacement). The mechanisms of labor, or cardinal movements of labor, describe the changes in the position of the fetal head as it travels through the birth canal. **The safe delivery of the infant is the goal of labor while decreasing maternal morbidity.**

ANATOMY AND PATHOPHYSIOLOGY

A successful vaginal delivery depends on the adequacy of the female pelvis. Pelvimetry may be used during prenatal visits to evaluate the adequacy of the pelvic space for fetal passage. Inadequate space may result in fetal entrapment, prolonged labor, and shoulder dystocia.³ The most useful planes for measurement are the pelvic inlet and the midplane (Figures 162-1A and 162-1B). The pelvic inlet is through measurement of the diagonal conjugate. The midplane is through measurement of the ischial interspinous or bi-ischial diameter.³

The diagonal conjugate refers to the distance from the inferior border of the pubic symphysis to the sacral promontory (Figure 162-1A). The normal diagonal conjugate measures approximately 12.5 cm, with the critical distance being 10 cm. Place the tip of the middle finger at the sacral promontory and note the point on the hand that contacts the pubic symphysis (Figure 162-1B). The true conjugate, a radiographic measurement of the pelvic inlet, represents the smallest diameter of the inlet from the sacral promontory to the superior aspect of the pubic symphysis (Figure 162-1A). It can be estimated by subtracting 1.5 to 2 cm from the diagonal conjugate and normally measures 11 cm or more (Figure 162-1A). The obstetric conjugate is the distance from the sacral promontory to a point on the inner surface of the pubic symphysis that is a few millimeters from the upper margin of the pubic symphysis (Figure 162-1A). This corresponds with the true conjugate and is approximately 11 cm.³ The midpelvis can be evaluated through measurement of the ischial interspinous diameter. Measure the distance between the ischial tuberosities (Figure 162-1C). A value greater than 10 cm is considered adequate.³

The assessment of maternal pelvic shape is generally not of clinical significance in the Emergency Department where patients will be delivering precipitously. Current clinical practice guidelines recommend a trial of labor as the fundamental way to determine whether a fetus will be able to pass through the maternal pelvis. Studies have suggested that the routine practice of pelvimetry is not effective in predicting the occurrence of cephalopelvic disproportion and is associated with an increase in rates of cesarean section.⁴⁻⁶

FETAL POSITIONING

Consider the anatomic position of the fetus in preparing for the successful delivery of an infant. This includes the fetal lie, fetal presentation, fetal station, and fetal position. Fetal lie may be a longitudinal, oblique, or transverse relationship between the longitudinal axis of the fetus in relation to the long axis of the mother. Fetal presentation defines the fetal part that can be felt during delivery. Infants will present in vertex or cephalic presentation most commonly. The Emergency Physician should be able to palpate the skull. An infant in a breech presentation will be in the longitudinal lie with the buttocks or feet first.

Fetal station refers to the relationship between the presenting part and the maternal ischial spines. Each number represents a centimeter in distance from the ischial spines. It is reported as a negative (i.e., from 0 to -5) if the presenting part lies above the ischial spines and positive (i.e., from 0 to +5) if it lies below the ischial spines. The fetus is considered “engaged” in the pelvis when it reaches the level of the ischial spines or 0 station.

The fetal position describes the relationship of the fetal presenting part (e.g., buttocks, foot, leg, or occiput) to the maternal pelvis (Figure 162-2). The position is best assessed by a sterile vaginal exam after the mother is completely dilated. The fetal occiput in the vertex presentation is used to determine the fetal position. Certain positioning (e.g., occiput posterior and occiput transverse) can make delivery more difficult. The different fetal vertex positions are noted in Figure 162-2.

CLASSIFICATION OF LABOR

The process of labor is divided into three stages and involves the repetitive uterine contractions that lead to cervical dilation and effacement. The first stage is the period between the onset of labor and complete cervical dilation. The second stage begins with complete cervical dilation and ends with the delivery of the infant. The third stage consists of the time between delivery of the infant and delivery of the placenta.

FIRST STAGE OF LABOR

The first stage of labor is further divided into three phases. The first or latent phase is the period between the onset of labor to cervical dilation of 3 to 4 cm. The second phase leads up to almost complete cervical dilation. During the third phase, maximum cervical dilation is achieved. The first stage of labor lasts approximately 8 hours in nulliparous women and 5 hours in multiparous women.

The American College of Obstetricians and Gynecologists (ACOG) recommends monitoring the fetal heart rate (FHR) during active labor by Doppler immediately following a contraction, every 30 minutes in low-risk pregnancies, and continuously

FIGURE 162-1. Measure pelvic distances to determine if there may be difficulties during the delivery. **A.** The pelvic conjugate diameters. **B.** Measuring the diagonal conjugate. **C.** The ischial interspinous distance.

FIGURE 162-2. Fetal presentations and positions in labor. **A.** Left occiput anterior (LOA). **B.** Left occiput transverse (LOT). **C.** Left occiput posterior (LOP). **D.** Right occiput anterior (ROA). **E.** Right occiput transverse (ROT). **F.** Right occiput posterior (ROP).

with high-risk pregnancies.⁷ Suspect fetal distress if the heart rate following a contraction is repeatedly below 120 beats per minute.⁸ Monitor the FHR following the contraction after the rupture of the membranes (ROM) to assess for occult umbilical cord compression.⁸

Contraction intensity is determined by the degree of firmness that the uterus achieves. Contractions may be palpated or monitored by an external transducer (i.e., tocodynamometer) placed upon the maternal abdomen. Monitor the maternal vital signs during active labor. Obtain a temperature at least every 2 hours and a blood pressure every 30 minutes.⁹ Antibiotic coverage for group B streptococcal infection is recommended in the case of prolonged ROM or membrane rupture lasting longer than 18 to 24 hours prior to the onset of labor.^{8,10,11} Perform a vaginal examination immediately after ROM if the fetal head is not engaged because of the possibility of a prolapsed umbilical cord.

■ SECOND STAGE OF LABOR

The second stage of labor begins with complete dilatation of the cervix and ends with delivery of the infant. It lasts approximately 50 minutes in nulliparous women and 20 minutes in multiparous women in an uncomplicated vaginal delivery. It is recommended that the FHR be auscultated at least every 15 minutes in low-risk infants and at least every 5 minutes in high-risk infants.⁷ FHR decelerations may occur with contractions as the head descends. Allow labor to progress if prompt recovery occurs as the contraction diminishes.⁷ Decelerations may occur from progressive compression of an umbilical cord around the fetus, premature placental separation, or reduction in uterine blood flow.¹² Prolonged

FHR decelerations are an indication for immediate cesarean section.^{7-9,11,12}

Bearing down is a natural reflex during the second stage of labor. Coaching may be helpful to optimize pushing efforts, especially in the presence of epidural anesthesia. Other techniques to optimize pushing efforts include flexing the maternal legs to 90° at the hips and knees, encouraging the patient to take a deep breath at the onset of a contraction and then push downward or Valsalva, and encouraging rest between contractions. Rest between contractions is needed for the mother and the fetus to recover from the effects of breath holding, muscular effort, and uterine contractions.⁸

The perineum will bulge as the fetus descends into the maternal pelvis. Sponge any expelled stool downward with a sterile sponge and diluted soap solution. Delivery is eminent when the scalp of the infant becomes visible at the introitus.

MECHANISM OF LABOR

The mechanism of labor or the cardinal movements of labor describe the process by which the fetal head optimally descends in relation to the maternal pelvis (**Figure 162-3**). They consist of engagement, descent, flexion, internal rotation, extension, external rotation, and expulsion (**Figure 162-4**).

The fetal head floats freely in the amniotic fluid before it engages the maternal pelvis (**Figure 162-4A**). The head is engaged when the widest diameter of the presenting part of the fetus (i.e., the biparietal diameter) passes below the plane of the pelvic inlet (**Figure 162-4B**). This can be confirmed clinically by palpation of the presenting part abdominally and vaginally. Bimanual examination will reveal the presenting part at station 0 or at the level of the maternal ischial spines. The head then descends into and through the maternal pelvis (**Figures 162-4B and 162-4C**). The greatest rate of descent occurs near the end of the active phase of labor.

The head flexes as it meets resistance from the cervix, pelvic floor, and pelvic walls during passage (**Figure 162-4B**). The smallest diameter of the fetal head (i.e., the suboccipitobregmatic diameter) passes passively through the maternal pelvis.

The fetal head then internally rotates causing the head to move anteriorly toward the pubic symphysis to assume the occiput anterior position (**Figures 162-4C and 162-4D**). It may rotate less commonly posteriorly toward the sacral hollow to assume the occiput posterior position. This too is a passive movement resulting from the contours of the maternal pelvis.

The fetal head then descends to the level of the introitus and begins to extend until the head is delivered (**Figures 162-4D and 162-4E**). A combination of the downward force of the contracting uterus and the upward force exerted by the maternal pelvic floor muscles rotates the fetal head in extension around the pubic symphysis. Extension continues until the fetal head is delivered.

The body externally rotates once the head is delivered. This brings the occiput and spine back into the same plane with the shoulders (**Figure 162-4F**). The body rotation can occur to either side depending upon the orientation of the fetus. The infant is then expelled or delivered. Anterior shoulder delivery precedes the delivery of the posterior shoulder in most cases (**Figures 162-4G and 162-4H**).

INDICATIONS

The indications for the performance of a vaginal delivery in the Emergency Department include a patient in active labor without the ability or time to transfer the patient to a delivery unit. The lack of an Obstetrician, Family Physician, Certified Nurse Midwife, or other obstetric practitioner will require the Emergency Physician to perform the delivery.

FIGURE 162-3. The mechanism of labor.

CONTRAINDICATIONS

There are no absolute contraindications to the emergent delivery of the fetus in the Emergency Department. Delivery is preferred in a well-staffed Obstetrics Department, especially when the delivery is complicated (e.g., breech presentations, prematurity, or a prolapsed umbilical cord).

EQUIPMENT

■ GENERAL SUPPLIES

- Electronic fetal monitor
- Sterile towels
- Povidone iodine or chlorhexidine solution
- Clock or timer watch
- Sterile perineal drapes
- Sterile gloves
- Needles, various gauges
- Syringes, various sizes
- Chromic suture, 2–0 and 4–0
- Vicryl suture, 2–0 and 3–0
- Bulb syringe

- Local anesthetic solution
- Clean towels or blanket for baby
- Umbilical cord clamp (**Figure 162-5**)
- Sterile scissors
- Infant warmer
- Infant resuscitation equipment

■ DELIVERY INSTRUMENT PACK

- Bandage scissors
- 4 towel clips
- 2 Allis forceps
- 4 ring forceps
- 6 straight Kocher clamps
- Straight Mayo scissors
- 2 suture scissors
- Adson forceps, or other forceps with teeth
- Russian forceps, 5.5 inches and 8 inches
- Gelpi retractor
- 2 small or medium Richardson retractors
- 2 Army-Navy retractors

FIGURE 162-4. The fetal movements associated with the mechanism of labor. **A.** The fetal head is floating free. **B.** The head has descended and flexed to engage in the pelvis. **C.** The head descends further and internally rotates. **D.** The head has completely rotated into the direct occiput anterior position. The head begins to extend. **E.** The head completely extends to allow it to be delivered. **F.** External rotation of the head to bring it back to its natural position. **G.** Delivery of the anterior shoulder. **H.** Delivery of the posterior shoulder.

- 2 needle holders, 6 inches
- Placenta basin

Prepackaged obstetric kits are readily available and should be stocked in the Emergency Department. They contain all the required equipment and supplies. These kits may be prepared and packaged by the hospital. Commercially produced, disposable kits are available from several manufacturers.

FIGURE 162-5. An umbilical clamp.

INITIAL ASSESSMENT

Obtaining as thorough a maternal history as possible. **It is important as part of the initial assessment to identify whether the gravid patient is truly in labor, the imminence of delivery, and any potential associated problems.** Perform Leopold maneuvers, bedside ultrasonography, a sterile vaginal examination, an evaluation to detect whether or not spontaneous ROM has occurred, and fetal monitoring.

TRUE LABOR VERSUS FALSE LABOR

True labor consists of contractions at regular intervals and that gradually increase with intensity. The interval between contractions decreases as labor progresses. Contractions cause discomfort in the back and upper abdomen. Physical examination reveals that the fetus has descended and the cervix is actively dilating and effacing.

False labor is common in late pregnancy. It is characterized by contractions that are brief, occur at irregular intervals, and with constant intensity. These are often referred to as Braxton-Hicks contractions. These contractions primarily cause discomfort in the lower abdomen. Physical examination often reveals the fetus has not descended and the cervix is not dilated. False labor contractions can be relieved by hydration and sedation.

HISTORY AND PHYSICAL EXAMINATION

Obtain a thorough history if the circumstance allows. Include gravity and parity, estimated gestational age, route of delivery for previous pregnancies (i.e., vaginal or surgical), the length of previous labor, and description of the contractions (i.e., frequency, onset, and strength). Estimate the number of weeks pregnant or estimated date of confinement. Did the patient experience bloody show, ROM, or any problems during this pregnancy? Did the patient have access to prenatal care? Does the patient have any general surgical and medical history? Inquire about allergies, blood type, and infectious disease history. Include prior herpes infections and human immunodeficiency virus (HIV) status. It is important to send a rapid HIV test if the HIV status is unknown.

The Centers for Disease Control and Prevention guidelines suggest treating for group B streptococcal (GBS) infection if the GBS status of the laboring mother is unknown and she is ≤ 37 weeks of gestation, has ROM ≥ 18 hours, or has a temperature $\geq 38.0^\circ\text{C}$.¹³ Treat mothers who have tested positive by GBS culture within 5 weeks of delivery, have had a previous newborn with GBS-invasive disease, or have a history of GBS bacteriuria during pregnancy.¹³

LEOPOLD MANEUVERS

Determine the fetal position and presenting part (i.e., vertex or breech) using the Leopold maneuvers (Figure 162-6). The fetus bends in late pregnancy so that its back is convex, the extremities and neck are sharply flexed, and the fetal arms are crossed across the chest (Figure 162-6A). This posture is assumed so that the growing fetus can fit within the uterine cavity. The lie of the fetus, or its long axis in comparison to the mother, is either longitudinal or transverse. Most fetuses lie in the longitudinal plane at term. Presentation describes the fetal part that is closest to the vagina as felt through the cervix. This is usually the head, but possibly the buttocks or feet if in a longitudinal lie.

Approximately 97% of fetuses will present in the vertex position at full term. The Leopold maneuvers can help to determine the position of the fetus by identifying specific fetal landmarks or the spatial relationship between the fetus and the mother (Figure 162-6). These maneuvers can be imprecise, especially in the hands of the unfamiliar. These maneuvers are only 28% sensitive when compared with ultrasonography for the verification of the fetal position.¹⁴ The use of the Leopold maneuvers has been largely replaced by bedside ultrasonography. They may still be useful when an Emergency Department ultrasound unit is not available.

The procedure involves multiple maneuvers, starting with the fundal grip to determine presentation. Stand at the patient's side facing her (Figure 162-6A). Gently palpate the abdomen with

the fingertips of both hands to determine which fetal part occupies the uterine fundus. The fetal head is firm, freely mobile, moves independent of the body, and is round and smooth. The fetal buttocks are less well-defined and can be felt as an irregular, large, and soft structure in the uterine fundus.

Perform the second maneuver or the umbilical grip. Stand at the patient's side facing her (Figure 162-6B). Place both hands on either side of the abdomen. Palpate deeply, firmly, and gently to identify the back as a smooth hard surface and the extremities (i.e., the small parts) as small nodular parts. Note the lie of the fetus and the position of the back.

Perform the third maneuver or Pawlik's grip. Stand at the patient's side facing her (Figure 162-6C). Place the thumb and middle finger of the dominant hand just above the pubic symphysis. Palpate to determine the presenting part and its relation to the fetal spine. The fetus will be in a vertex or occiput presentation if the cephalic prominence is palpable on the same side as the small parts (i.e., the head is flexed). The fetus will be in a forehead presentation if the cephalic prominence is palpable on the same side as the spine (i.e., the head is extended). The fourth maneuver must be performed to determine the presentation if the presenting part is fixed and deep within the pelvis.

The fourth maneuver or pelvic grip can determine the degree of flexion of the fetal head. Stand at the patient's side facing her feet (Figure 162-6D). Place the tips of the thumb, index, and middle fingers over both sides of the lower abdomen. Palpate deeply, firmly, and gently toward the pelvic inlet with both hands. Determine the head position in relation to the fetal spine and small parts.

ULTRASOUND FOR FETAL PRESENTATION

Confirmation of vertex position by bedside ultrasound can be performed by placing the abdominal transducer transversely in the suprapubic region. Orient the transducer indicator directed to the maternal right side. Fan the transducer caudally to identify the presenting part. The fetal head will be low in the pelvis. The fetal skull will be visible as a hyperechoic, bright white oval image (Figure 162-7). Ensure that this is the fetal head rather than a cross-section of abdomen which can also appear as a bright white circular to oval-shaped image. Rotate the ultrasound transducer 90° to visualize the fetal skull in a second plane and visualize the fetal head articulating with the trunk.

STERILE VAGINAL EXAMINATION

A sterile vaginal examination is crucial to accurately assess a woman in labor. It will evaluate dilation, effacement, station, fetal position, and the presence of blood. **Always use sterile gloves to decrease the**

FIGURE 162-6. Leopold's maneuvers. **A.** The first maneuver. **B.** The second maneuver. **C.** The third maneuver. **D.** The fourth maneuver.

FIGURE 162-7. Transabdominal ultrasound of the lower abdomen of a gravid woman. The brightly echogenic fetal skull bones are visualized indicating a vertex presentation.

risk of infection. Vaginal bleeding that exceeds a bloody show is a contraindication to a digital vaginal examination.

Examine the cervix for dilatation and effacement. **Effacement** is said to be 50% when the length of the cervix is one-half (i.e., approximately 2 cm long) that of an uneffaced cervix (i.e., approximately 4 cm long). It is said to be completely or 100% effaced when the cervix becomes as thin as the lower uterine segment. **Dilation** is an estimate of the cervical opening expressed in centimeters. Place two fingers in the vagina and spread them apart until the walls of the cervix are appreciated. Use the distance between the fingers to determine the dilation of the cervix in centimeters. The cervix is completely dilated (i.e., approximately 10 cm) when no cervix can be palpated around the presenting part. Use caution in declaring the patient fully dilated once the cervix has dilated beyond the ability of the fingers to spread apart. **Take extra care to palpate the circumference of the presenting part.** Ensure that no cervix is appreciated by palpating the circumference of the presenting part (i.e., the occiput) to avoid falsely declaring a patient fully dilated.

Assessment of the station of the fetal head is vital for understanding how far the fetus has descended. It measures how many centimeters the fetal occiput is above or below the maternal ischial spines. The classification system ranges from -5 cm to +5 cm. Zero station is when the occiput reaches the level of the maternal ischial spines, negative station (i.e., -1 cm to -5 cm) when the fetal head is above the level of the maternal ischial spines, and positive station (i.e., +1 cm to +5 cm) when the fetal head is below the level of the maternal ischial spines.

DETECTION OF RUPTURED MEMBRANES

ROM can be determined by the speculum exam and specific testing. Look for fluid accumulation or pooling in the posterior vaginal fornix during the sterile speculum examination. Swab the pooled fluid and examine it for ferning, Nitrazine positivity, and the presence of meconium.

Determine the pH of the pooled fluid by touching a sample of the pooled fluid to pH or Nitrazine paper. Amniotic fluid is basic (i.e., pH 7.0 to 7.5), whereas the vagina and its secretions are acidic (i.e., pH 4.5 to 5.5). The pooled fluid is presumed to be amniotic fluid if the color of the Nitrazine paper changes from yellow to blue. Blood is also basic and may give a false-positive result if the sample is contaminated.

The final diagnostic test for ROM and the most specific way to identify ROM is the ferning test. Place a sample of the pooled fluid on a slide and allow it to air dry. Examine the slide under a microscope. The crystals that make up the amniotic fluid will arborize giving the appearance of fern leaves and thus a positive test if the fluid is amniotic fluid.

FETAL ASSESSMENT

The FHR is between 120 and 160 beats per minute. It can be assessed by auscultation, Doppler, or electronic fetal monitoring (EFM). The ACOG has issued guidelines regarding continuous fetal monitoring.⁷ The false-positive rate of EFM for predicting an adverse outcome is high.⁷ The use of EFM is associated with an increase in the rate of operative interventions (i.e., cesarean, forceps, and vacuum delivery) due to a high false-positive rate of EFM for predicting an adverse outcome.

EFM is unnecessary for most straightforward and low-risk deliveries but is standard practice.⁷ An understanding of how to interpret the FHR is important.⁷ The first step is interpreting the tracing for variability which reflects intact neuromodulation of the heart rate and that the cardiovascular system is robust. **Variability is the beat to beat irregularity in the tracing that gives the appearance of a wavy baseline.** Variability can be further characterized as absent, minimal, moderate, or marked. Absent variability shows no changes in amplitude from the baseline. Minimal variability shows ≤ 5 beats per minute (bpm) change. Moderate variability shows 6 to 25 bpm change. Marked variability shows ≥ 25 bpm change. Decreased variability is a sensitive finding and may represent benign processes (e.g., fetal sleep) or more concerning etiologies (e.g., acidosis and hypoxia).¹¹

Evaluate the EFM tracing for any accelerations (**Figure 162-8**). These represent fetal movement and are defined as an increase above the baseline of 15 bpm lasting for 15 seconds. The presence

FIGURE 162-8. Acceleration recorded on the electronic fetal monitoring strip. (Reproduced with permission from Pearlman MD et al: *Obstetric & Gynecologic Emergencies: Diagnosis and Management*. New York: McGraw-Hill; 2004.)

FIGURE 162-9. Late deceleration recorded on the electronic fetal monitoring strip. (Reproduced with permission from Pearlman MD et al: *Obstetric & Gynecologic Emergencies: Diagnosis and Management*. New York: McGraw-Hill; 2004.)

of accelerations provides reassurance that the fetus is healthy and withstanding the stress of labor.¹¹

Evaluate the EFM tracing for decelerations. The two main types are late and variable decelerations. Late decelerations are a sign of fetal hypoxia. They are characterized as a gradual fall and rise, shallow, symmetric, and U-shaped (**Figure 162-9**). They usually begin 30 seconds after the onset of a contraction. The nadir of the deceleration occurs after the peak of the contraction. Variable decelerations are the most common type of deceleration encountered during labor and signify compression of the umbilical cord. They are variable in duration, shape, size, and timing relative to the contraction (**Figure 162-10**). Their onset and resolution are generally abrupt and sharp. Variable decelerations are usually preceded and followed by an acceleration.¹¹

PATIENT PREPARATION

An important first step is to obtain the vital signs of the mother if time allows during a precipitous delivery. Assess FHR if fetal monitoring is available. Explain to the mother the indication for emergent delivery in the Emergency Department including the risks and benefits (**Table 162-1**). Explain what to expect, the procedures that may be performed, and attempt to incorporate maternal cooperation to accomplish a controlled delivery.^{15,16} Obtain intravenous access. Send samples of blood and urine to the laboratory to determine a hematocrit, urine protein, blood type, Rh status, antibody screen, Venereal Disease Research Laboratory (VDRL), rapid HIV, and hepatitis screen. Do not give the patient anything to eat or drink once she enters the Emergency Department since gastric emptying is delayed in pregnancy.

The most commonly used maternal position for delivery is the dorsal lithotomy position (**Figure 162-11**). This position increases the diameter of the pelvic outlet. Place the patient supine with her legs in stirrups or leg holders. Be sure not to strap the legs so that

quick flexion of the thighs can occur if shoulder dystocia presents. Cleanse the vulvar and perineal area with sterile soap, povidone iodine solution, or chlorhexidine solution if time permits. Apply sterile drapes to only expose the vulvar area (**Figure 162-11**). Full sterile technique is not required. Don sterile gloves, a sterile gown, and a mask with eye protection.

Perineal infiltration with a local anesthetic can safely and effectively provide pain relief during vaginal delivery. A pudendal nerve block is a minor regional block that provides adequate analgesia (**Figure 162-12A**). Apply a needle guard onto the middle finger. Palpate the ischial spine through the vagina. Insert a 20 gauge needle between the index and middle finger (**Figure 162-12B**). Advance the needle and pierce the sacrospinous ligament (**Figure 162-12B**). Aspirate to ensure that the tip of the needle is not within a blood vessel. Inject 5 to 10 mL of local anesthetic solution. Repeat this procedure on the contralateral side.

The pudendal nerve block does not eliminate sensation from the anterior perineum. This area is supplied from branches of the genitofemoral nerve and ilioinguinal nerve. The pudendal nerve block does not eliminate uterine contraction pain. The uterus is supplied by sympathetic fibers from T12-L2. The uterus does not relax with a pudendal nerve block. Allow 5 to 20 minutes for the block to take effect.

A paracervical block can also be used to provide analgesia. It anesthetizes the Frankenhäuser ganglions that contain all the visceral sensory nerve fibers from the uterus, cervix, and upper vagina. It can only be used during the first stage of labor. Apply a needle guard onto the middle finger. Palpate the lateral vaginal fornix (**Figure 162-13**). Insert a 20 gauge needle along the middle finger (**Figure 162-13**). Advance the needle into the submucosa of the lateral vaginal fornix. Aspirate to ensure that the tip of the needle is not within a blood vessel. Inject 5 to 7 mL of local anesthetic solution. Repeat this procedure on the contralateral side. Paracervical block anesthesia has been associated with a relatively high

FIGURE 162-10. Variable decelerations recorded on the electronic fetal monitoring strip. (Reproduced with permission from Pearlman MD et al: *Obstetric & Gynecologic Emergencies: Diagnosis and Management*. New York: McGraw-Hill; 2004.)

incidence of fetal bradycardia, usually developing 2 to 10 minutes after the block.

TECHNIQUE

DELIVERY OF THE INFANT

Coaching may be required for optimal pushing efforts. Flex the patient's legs at the hips and knees to increase and improve pushing efficacy. Encourage the patient to take a deep breath at the onset of a contraction and then push downward or Valsalva. Advise rest between contractions as she and the fetus need to recover

**FIGURE 162-12.** The pudendal nerve block. **A.** The area of sensory innervation of the pudendal nerve. **B.** Infiltration of local anesthetic solution.

from the effects of breath holding, muscular effort, and uterine contractions. The perineum will bulge as the fetus descends into the maternal pelvis. Sponge downward any expelled stool with a sterile towel or piece of gauze. The patient and the fetus are prepared for delivery when the scalp of the fetus becomes visible at the introitus.

The fetal head becomes increasingly visible at the introitus as labor progresses. Apply gentle downward pressure on the occiput to aid in the controlled delivery of the head once the bony occiput can be seen and palpated at the vaginal introitus. The fetal head stretches the vaginal outlet and the vulva until they encircle the largest diameter of the fetal head, known as crowning. Gentle digital stretching of the inferior portion of the perineum may aid delivery. The routine use of an episiotomy for delivery has been discouraged due to increases in third-degree and fourth-degree lacerations.¹⁷ **Perform an episiotomy when the baby is crowning if there appears to be inadequate stretching of the perineum (Chapter 163).**

Apply manual perineal support and control the head by performing the modified Ritgen maneuver as the fetal head emerges from the introitus (**Figure 162-14**). Apply a towel-draped hand to protect against fecal contamination. Apply pressure on the fetal chin through the perineum anterior to the maternal coccyx. Place the other hand on the fetal occiput to hold the suboccipital region against the maternal pubic symphysis. It was thought that this maneuver helps to extend the fetal neck, ease the delivery of the fetus, and reduce the incidence of third-degree and fourth-degree perineal lacerations. A study did not show a decrease in perineal lacerations with this technique.¹⁸ **It is important to control the speed at which the fetal head delivers and ease the pressure on the perineum to decrease perineal tears.**

Encourage less forceful pushing after crowning occurs to control delivery of the head and to minimize perineal trauma. Slowly deliver the fetal head using the modified Ritgen maneuver.^{8,11} The base of the occiput will rotate, or restitute, toward the posterior aspect of the

FIGURE 162-14. The modified Ritgen maneuver. A hand covered with a sterile towel applies moderate upward pressure on the perineum between the anus and the introitus. The other hand extends the fetal head to maintain the suboccipital region against the maternal pubic symphysis. This maneuver assists in the delivery of the fetal head.

FIGURE 162-15. Slip any loops of umbilical cord that are wrapped around the fetal neck over the head.

maternal pubic symphysis while the fetal brow, face, and chin pass over the maternal perineum. Instruct the mother to stop pushing once the head is delivered. Gently rotate the infant's head slightly if it does not spontaneously rotate. **The routine intrapartum and peripartum suctioning of the nasal cavities and oropharynx of infants with or without meconium-stained amniotic fluid is no longer recommended.**¹⁹⁻²²

Pass one hand around the neck of the fetus to assess for a nuchal cord which occurs in approximately 25% of deliveries.^{8,11,12} **Unwind the umbilical cord from the fetal neck prior to continuing with the delivery.**¹² Slip it over the infant's head if possible (**Figure 162-15**). The umbilical cord can occasionally be wrapped so tightly around the fetal neck that it cannot be slipped over the head. **Carefully grasp and clamp the umbilical cord between two hemostats or umbilical clamps placed 1 to 2 cm apart. Carefully cut the umbilical cord between the two clamps with sterile scissors. Unwind the umbilical cord from around the fetal neck. Immediately deliver the fetus as it no longer can rely on the maternal circulation once the umbilical cord is clamped and cut.**

Deliver the body of the fetus (**Figure 162-16**). Gently grasp the sides of the fetal head with two hands (**Figure 162-16**). Apply steady and gentle downward traction until the anterior shoulder appears under the maternal pubic symphysis (**Figure 162-16A**). Apply steady and gentle upward traction until the posterior shoulder is delivered (**Figure 162-16B**). **The use of gentle traction with both of these maneuvers is important to avoid brachial plexus injuries.**

The rest of the infant will spontaneously deliver once the shoulders are delivered. **It is still very important to control the delivery of the body to prevent maternal perineal lacerations.** A combination of amniotic fluid, blood, and vernix makes delivery of the infant very slippery. Proper hand positioning is important during the delivery of the body. Position the posterior or left hand underneath the infant's axilla prior to delivering the rest of the body. Use the anterior or right hand to grasp the infant's ankles as they are delivered. This ensures a firm grip on the infant.

Place two hemostats or umbilical clamps on the umbilical cord approximately 4 to 5 cm from the infant and 1 cm apart. Cut the

FIGURE 162-16. Delivery of the body. Grasp the head with both hands. **A.** Apply gentle and steady downward traction to deliver the anterior shoulder. **B.** Apply gentle and steady upward traction to deliver the posterior shoulder.

umbilical cord between the two clamps using sterile scissors. Obtain a 10 to 20 mL sample of umbilical cord blood from the placental end for cord blood pH to determine fetal acid-base status and other required tests.¹⁹

It is now recommended to delay umbilical cord clamping for at least 30 to 60 seconds after birth in term and preterm uncomplicated deliveries.^{20,23} This has been found to increase hemoglobin levels at birth and improve iron stores in the first several months of life. This may have a favorable effect on developmental outcomes. It is associated with significant neonatal benefits in preterm infants including improved transitional circulation, better establishment of red blood cell volume, decreased need for blood transfusion, and lower incidence of necrotizing enterocolitis and intraventricular hemorrhage. There is no increased risk of postpartum hemorrhage. There is a small increase in the incidence of jaundice that requires phototherapy in term infants undergoing delayed umbilical cord clamping. This requires that the Emergency Physician ensure that mechanisms are in place to monitor and treat neonatal jaundice.²⁰

Dry the infant while simultaneously stimulating and assessing for appropriate physiologic responses. The mother may immediately hold the infant and breastfeed, if desired, while the umbilical cord is being cut in an uncomplicated birth. The infant should respond well to initial stimulation and have an adequately clear airway and good respiratory effort. The infant can be further dried and stimulated in a warm incubator if necessary. **Calculate the APGAR scores at 1 minute and 5 minutes after delivery.** Repeat the APGAR score every 5 minutes in the immediate postpartum period if the APGAR score is low at 5 minutes. The acronym **APGAR** was coined as a mnemonic learning aid. It stands for Appearance (skin color), Pulse (heart rate), Grimace (reflex irritability), Activity (muscle tone), and Respiration (Table 162-2).

TABLE 162-2 The APGAR Score

Sign	Score = 0	Score = 1	Score = 2
Skin color (Appearance)	Blue or pale	Pink body and blue extremities	Completely pink
Heart rate (Pulse rate)	Absent	Slow (< 100)	> 100
Reflex irritability (Grimace)	No response	Grimace	Vigorous crying
Muscle tone (Activity)	Flaccid	Some extremity flexion	Active motion
Respiratory effort (Respiration)	Absent	Slow or irregular	Good and crying

Note: Add the scores for each of the five signs to obtain the infant's APGAR score. The maximal possible score is 10. Scores less than 7 are considered low.

MATERNAL AND FETAL MONITORING

The ACOG recommends that providers evaluate and record the FHR at least every 30 minutes in the active phase of the first stage of labor and every 15 minutes in the second stage in patients without complications or risk factors.⁷ The ACOG recommends continuous FHR monitoring if the delivery is complicated (e.g., suspected fetal growth retardation, preeclampsia, and type 1 diabetes).⁷ Evaluate and record the FHR at least every 15 minutes in the active phase of the first stage of labor and every 5 minutes in the second stage if continuous monitoring is not possible.⁷

Suspect fetal distress if the FHR following a contraction is repeatedly below 120 bpm. Place the mother on oxygen, move her to the left lateral decubitus position, and check for umbilical cord prolapse in the absence of vaginal bleeding if fetal distress is appreciated. FHR decelerations may occur with contractions as the head descends. Allow labor to continue if prompt recovery occurs as the contraction diminishes. Decelerations may also occur from progressive compression of the umbilical cord around the fetus, premature placental separation, or reduction in uterine blood flow.¹² These can lead to fetal compromise.¹² Prolonged FHR decelerations are worrisome and warrant action (e.g., supplemental maternal oxygen, repositioning of the mother, and immediate delivery of the baby by cesarean section).⁷

The intensity of a contraction is determined by the degree of firmness that the uterus achieves. The frequency of contractions may be palpated or monitored by an external transducer (i.e., tocodynamometer) placed upon the mother's abdomen. **Remember to monitor the maternal vital signs during active labor and intervene as needed when abnormal vital signs present themselves.**

DELIVERY OF THE PLACENTA

Watchful waiting until the placenta separates from the uterus is an acceptable practice if there is no unusual bleeding after delivery of the infant. Watch for the signs of placental separation during expectant management. These include a firm and globular uterus, a sudden gush of blood, uterine elevation in the abdomen, and a lengthening of the umbilical cord. This usually occurs within 5 to 10 minutes after delivery of the infant. It may take as long as 30 minutes. Times longer than 30 minutes raise concern for a retained placenta.

Some may choose to actively manage the third stage of labor by clamping the umbilical cord, applying controlled umbilical cord

traction, and administering a uterotonic drug (e.g., oxytocin) to stem postpartum hemorrhage.^{24,25} The literature is mixed with respect to whether active management of labor is beneficial when compared to expectant management.²⁴⁻²⁶ **Pulling too hard on the umbilical cord can invert the uterus and make postpartum hemorrhage worse.**²⁷

Instruct the patient to bear down once the placenta has separated. This results in increased intraabdominal pressure that aids in delivery of the placenta. Apply suprapubic pressure (**Figure 162-17A**). Apply gentle traction on the umbilical cord to keep it taut without the use of excessive traction (**Figure 162-17A**). **Aggressive traction on the umbilical cord can result in disruption of the placenta, uterine inversion, or tearing of the umbilical cord.**²⁷ **All these can result in excessive bleeding.** Applying suprapubic pressure as the placenta exits the uterus helps to prevent uterine inversion (**Figure 162-17B**). Deliver the placenta from the uterus (**Figure 162-17C**). Take care to prevent tearing of the placenta and its membranes as it passes through the introitus. Grasp the placenta and membranes with hands or ring forceps and guide them out the vagina with gentle twisting traction (**Figure 162-17D**). Gently massage the uterus through the anterior abdominal wall.^{17,28} **Carefully examine the maternal surface of the placenta for completeness. Any missing pieces represent retained products and must be removed.**

ALTERNATIVE TECHNIQUES

Operative vaginal delivery involves the use of forceps or vacuum extractors. This mode of delivery is sometimes controversial but it can be a safe and effective technique for delivery.^{8,11} The use of forceps and vacuums is beyond the scope of this chapter.

ASSESSMENT

Vaginal lacerations are classified as first, second, third, or fourth degree.^{8,11} First-degree lacerations involve the fourchette, perineal skin, and vaginal mucous membrane but not the underlying fascia or muscle. Second-degree lacerations involve the above plus the fascia and muscles of the perineal body but not the anal sphincter. Third-degree lacerations involve the anal sphincter and fourth-degree lacerations extend through the anal mucosa. The repair of vaginal lacerations is beyond the scope of this chapter. Refer to Chapters 163 and 166 for the complete details regarding laceration repair. Resuscitate the mother if necessary. This includes positioning on the left side in Trendelenburg position.²⁹

Assess the infant. Determine the APGAR score (**Table 162-2**). Repeat this every 5 minutes until the infant is stable. Place the infant in a warmer. Warm, dry, and stimulate the infant, and resuscitate as necessary.^{1,2,30,31} Resuscitate the infant immediately and do not stop

FIGURE 162-17. Delivery of the placenta. **A.** Apply gentle traction on the umbilical cord. **B.** Apply suprapubic pressure to help expel the placenta and prevent inversion of the uterus. **C.** Delivery of the placenta. **D.** Torn membranes or placenta are grasped with a ring forceps and delivered.

until the decision is made that the infant is not viable. This may include suction, intubation, chest compression, vascular access, and tube thoracotomy.

AFTERCARE

The hour immediately following delivery is a critical time and often referred to as the fourth stage of labor. The mother is at risk for hemorrhage from uterine atony or lacerations of the birth canal. **Investigate any unusual bleeding immediately.** Administer 20 units of oxytocin in 1 L of normal saline intravenously to prevent uterine atony and postpartum hemorrhage. Persistent vaginal bleeding can be managed with additional intravenous oxytocin, 0.2 mg of methylergonovine (Methergine) intramuscularly, or 0.2 mg of prostaglandin F₂-alpha (Hemabate) intramuscularly (Chapter 166).

COMPLICATIONS

Numerous complications can result during the delivery of an infant. These may affect the infant, the mother, or both.

UMBILICAL CORD PROLAPSE

Do not remove the hand if the initial vaginal examination reveals a prolapsed umbilical cord. Elevate the fetal presenting part away from the prolapsed umbilical cord and place the patient in the Trendelenburg position. This reduces compression of the umbilical cord and optimizes blood flow to the fetus. **Immediately transport and prepare the patient for an emergent cesarean section while keeping the hand in place.**

SHOULDER DYSTOCIA

The shoulders may occasionally impact at the pelvic outlet after delivery of the head. This is more likely to occur in large infants who have larger shoulders compared to their head circumference. Complications of shoulder dystocia include brachial plexus injuries, fetal hypoxia, and umbilical cord compression. Place the mother in the extreme lithotomy position with her legs sharply flexed up to the abdomen (i.e., McRoberts maneuver). An episiotomy may be made to assist in the delivery (Chapter 163). Instruct an assistant to apply suprapubic pressure to help disimpact the anterior shoulder from the pubic symphysis. Refer to Chapter 164 for the complete details regarding the management of shoulder dystocia.

BREECH PRESENTATION

The breech presentation is associated with a higher incidence of fetal distress and umbilical cord prolapse. It usually occurs in premature infants as the final rotation in the uterus may have not yet occurred. The major concern of breech deliveries is entrapment of the head because of an incompletely dilated cervix. **Do not pull on the fetus. This may put additional pressure on the head or further entrap an extremity. Obtain immediate Obstetrical assistance.** Refer to Chapter 165 for the complete details regarding breech deliveries.

PRETERM DELIVERY

Delivery of the preterm fetus must be controlled and slow to reduce the likelihood of trauma to the fragile infant. Immediately dry and warm the preterm infant while making an initial assessment. Begin

resuscitation even for extreme prematurity until the determination of viability is made.

POSTPARTUM HEMORRHAGE

Significant bleeding can occur from cervical lacerations, uterine atony, retained products, or first-degree through fourth-degree lacerations.¹⁷ Perform a thorough search for the cause of the postpartum hemorrhage. Refer to Chapter 166 for the complete details regarding the evaluation and management of postpartum hemorrhage.

INJURIES TO THE INFANT

A variety of injuries can occur to the fetus during the delivery process. These include abrasions, brachial plexopathies, bruising, clavicle fractures, cephalohematomas, femur fractures, humerus fractures, intracranial hemorrhage, lacerations, nerve injuries, skull fractures, spinal cord injuries, and visceral injuries. Most of these can be prevented by using appropriate techniques and care when delivering the infant.

SUMMARY

The Emergency Physician will occasionally be required to perform a delivery of a baby when the Obstetrician or Family Physician is not available or when delivery is imminent. Fortunately, births in the Emergency Department are rare and most proceed with good outcomes. Knowledge of the normal labor and delivery mechanics aids in a safe delivery and helps to identify complications. The Emergency Physician must develop strategies to treat potential complications and must be prepared to intervene. It is important to remember there are two patients.

Episiotomy

Francisco Orejuela and Padraic Chisholm

INTRODUCTION

An episiotomy is a surgical incision of the female perineum performed at the time of delivery to increase the diameter of the soft tissue pelvic outlet and facilitate a vaginal delivery. It is one of the most commonly performed surgical procedures in women in the United States yet it is controversial.

The episiotomy was thought to provide protection to the female genital tract and to facilitate an easier vaginal repair compared to a spontaneous laceration.^{1,2} It is thought to prevent perineal tearing by substituting a straight surgical incision for a ragged spontaneous laceration that may have a worse outcome after repair. It was also believed that an episiotomy resulted in decreased postoperative pain and improved healing when compared to a tear. These original beliefs have been challenged. There is a growing body of evidence

demonstrating increased injury to the pelvic floor with the routine use of an episiotomy.³⁻⁶ A Cochrane database review of eight randomized controlled trials concluded that a restrictive use of an episiotomy lowers the incidence of posterior perineal trauma, decreases the amount of suturing, and results in fewer complications as compared to routine episiotomy.⁷ Current recommendations favor a restrictive use of episiotomy.^{8,9} The rate of episiotomy has steadily declined in the recent decades. As an example, the rates of episiotomy between 2006 and 2012 decreased from 17.3% to 11.6% in a cohort of 2.3 million women.¹⁰

There is a place for the episiotomy in modern obstetrics. The indications for an episiotomy today are based primarily on the clinical situation at the time of delivery (e.g., need to expedite delivery for suspected non-reassuring fetal status). Another important reason to make an episiotomy is the prevention of a long and irregular spontaneous perineal laceration. The repair of a controlled surgical incision might be easier and the anatomic planes easier to recognize. Good clinical judgment is still the best guide to use to determine whether or not to proceed with an episiotomy.¹¹

ANATOMY AND PATHOPHYSIOLOGY**ANATOMY OF THE PERINEUM**

The perineum is a diamond-shaped region bounded by the bony structures of the pelvic outlet (i.e., the pubic symphysis, inferior pubic rami, and coccyx). An important anatomic area in obstetrics is the perineal body. It is located toward the center of the perineum between the lower vagina and the anus. The most critical area of the perineum is the distance from the vestibular fossa to the anus. It is usually 3 to 4 cm in length in the nonpregnant woman.^{11,12} The perineal body is a complex fibromuscular mass into which many structures insert.

The perineal body is the center of the hub of a wheel that includes the transverse perineal muscles, the capsule of the external anal sphincter muscle, and the bulbospongiosus muscle (**Figure 163-1**). The perineal body attaches to the ischial tuberosities and to the inferior pubic rami through the perineal membrane and superficial transverse perineal muscles. The bulbospongiosus muscles are located laterally to the introitus and deep to the labia majora. They insert into the inferior limit of the perineal body with the superficial transverse muscles and the subcutaneous portion of the external anal sphincter. The bulbospongiosus muscles are attached laterally to the muscles of the pelvic diaphragm. The perineal body is anchored posteriorly to the coccyx by the anal sphincter and anococcygeal ligament. The mediolateral episiotomy transects the superficial muscles of the perineum whereas the midline episiotomy does not. The pudendal nerve supplies most of the innervation to the perineal body. This nerve is formed from the ventral rami of sacral spinal nerves two through four. The arterial supply is primarily derived from the internal pudendal artery, one of the branches of the anterior trunk of the internal iliac artery.¹¹

TYPES OF EPISIOTOMY

An episiotomy is a surgical enlargement of the posterior vagina by an incision into the perineum and may be performed in the midline or mediolaterally (**Figure 163-2**).¹³⁻¹⁷ The choice between the two types of episiotomy is largely dependent upon the experience of the Emergency Physician. Factors that influence type of episiotomy include the site of prior episiotomies, position of the presenting fetal part, the thickness or rigidity of the patient's perineum, and the increased likelihood of a severe perineal laceration (e.g., in patients with a short perineal body and the use of forceps for vaginal delivery). A mediolateral incision may be prudent when an extended

FIGURE 163-1. The anatomy of the perineum. The skin and subcutaneous tissues have been removed.

episiotomy is required or when the risk of a fourth-degree laceration is significant.¹⁸⁻²⁰ **Never perform any other episiotomy incision in the Emergency Department. These are associated with significant complications.**¹⁴ Reserve the numerous other episiotomy incisions for the Obstetrician.²¹

FIGURE 163-2. The types of episiotomies for the Emergency Physician. **A.** Midline. **B.** Mediolateral. (Photo used with permission from reference 13.)

MIDLINE EPISIOTOMY

The midline episiotomy is a surgical incision made in the midline of the perineal body starting from the vaginal orifice toward the anus (**Figure 163-2A**). The incision transects the central tendinous portion of the perineal body and usually extends to the level of the transverse perineal muscle (**Figure 163-1**). The incision should run halfway between the posterior fourchette and anus. This is the most common type of episiotomy performed in the United States. The midline episiotomy is easy to perform and to repair. It is associated with quicker healing, less pain, less postpartum discomfort since no muscle belly is transected, quicker return to sexual intercourse, and less blood loss. There is an increased risk of third-degree and fourth-degree extensions with the midline episiotomy when compared to mediolateral episiotomies.

MEDIOLATERAL EPISIOTOMY

The mediolateral episiotomy is the preferred technique outside the United States.²² The mediolateral episiotomy is a surgical incision made from the midline of the posterior vaginal orifice obliquely toward the ischial tuberosity (**Figure 163-2B**). The anatomic structures transected from superficial to deep are the skin, the subcutaneous tissues, the bulbospongiosus muscle, the superficial transverse perineal muscle, and a portion of the levator ani muscle and fascia.

The mediolateral episiotomy is the preferred technique when considering an operative vaginal delivery. It is associated with a decreased risk of extension to the anal sphincter which is associated with fecal incontinence.²³⁻²⁵ The disadvantages of the mediolateral episiotomy include increased blood loss, increased postpartum discomfort, faulty healing, anatomic deformities, and dyspareunia.^{6,18-20} The adequate surgical repair of these structures requires an understanding of the perineal anatomy and represents a higher degree of difficulty to repair.

PERINEAL LACERATIONS

The classification of perineal lacerations most often used is quite simple.²⁶ A first-degree laceration is a superficial laceration of the vaginal epithelium not requiring suturing. A second-degree laceration or episiotomy involves the vaginal epithelium and the perineal body but does not include the anal sphincter complex (i.e., external anal sphincter and internal anal sphincter). It typically requires suture closure. The third-degree laceration or episiotomy is an extension of the laceration to involve any part of the anal sphincter complex. The fourth-degree laceration or episiotomy is an extension to the anal sphincter complex and anal mucosa.

INDICATIONS

The rate of episiotomy decreases as one travels the continuum from Obstetrician to Family Practitioner to Certified Nurse Midwife to lay Midwife. The indications for episiotomy are more largely based on expert consensus than evidence-based criteria. The indications depend on the clinical picture at the time of delivery.²⁷ Most practitioners consider the performance of an episiotomy to be appropriate in situations of fetal distress or maternal disease requiring urgent delivery.⁸ Deliveries necessitating greater space accommodation for effective delivery are also indications for an episiotomy. These situations include shoulder dystocia, breech delivery, or operative vaginal deliveries.²⁷⁻²⁹ Mediolateral episiotomies are the preferred method to avoid extension into the anal sphincter for operative deliveries.

CONTRAINDICATIONS

Contraindications to performing an episiotomy include rectal or perineal lesions, prior or concurrent fistulae, inflammatory bowel disease, or prior anorectal surgery.³⁰ Maternal diseases that impair healing such as autoimmune disorders (e.g., systemic lupus erythematosus, rheumatoid arthritis), HIV, pregestational diabetes mellitus, and immunosuppression are relative contraindications to an episiotomy. Some authors suggest that coagulation disorders may be contraindications; however, a vaginal delivery with an episiotomy is preferable to a cesarean delivery.¹⁴

EQUIPMENT

- Local anesthetic solution (e.g., lidocaine or bupivacaine)
- Alcohol wipes
- 16 to 18 gauge needle
- 10 mL syringe
- 22 to 25 gauge needle
- Mayo scissors
- #10 scalpel blade on a handle
- Povidone iodine or chlorhexidine solution
- Sterile drapes
- Sterile gown and gloves
- 2-0 polyglactin suture (i.e., Vicryl)
- 2-0 or 3-0 polydioxanone (i.e., PDS) and 3-0 Vicryl
- Needle driver
- 23 gauge spinal needle for possible pudendal nerve block

The incision of 60° is required for the achievement of a 45° postdelivery angle due to the perineal distention from crowning.²⁴ The recommended safest cutting angle is 60°. Midwives and doctors perform a true mediolateral incision in most cases.^{31,32} The Emergency Physician does not have much experience making an

A

B

FIGURE 163-3. The Episissors-60. **A.** The scissors. **B.** Use on a manikin. (Photos courtesy of D. Kapoor, MD.)

episiotomy incision. It can be expected that the Emergency Physician will not make an incision at the correct angle. Approximation of or eyeballing the incision does not work in most cases. The Episissors-60 (Medinvent Ltd, United Kingdom) solves this problem (**Figure 163-3**).³³⁻³⁵ The guide limb is positioned at the anus. The blades are fixed at a 60° angle from the guide limb. Sutured angles after delivery are between 40° and 52°. These special scissors are not often found in the Emergency Department. Hopefully, they will soon be contained in the hospital delivery kit.

PATIENT PREPARATION

Explain the risks, benefits, and alternative procedures to the patient and/or their representative. Obtain an informed consent for the procedure and place this in the medical record. Clean the perineum of any dirt, debris, stool, and urine. Apply povidone iodine or chlorhexidine solution and allow it to dry. Place sterile drapes beneath the buttocks, over the legs, and on the abdomen to prevent contamination from nonsterile areas.

Anesthetize the perineal body (**Figure 163-4A**). Infiltrate 10 to 20 mL of local anesthetic solution directly into the perineal body from the posterior base of the vaginal fourchette to the anus (**Figure 163-4A**). This provides safe and effective anesthesia. It may be carefully performed if the baby's head is within the vagina or crowning. The application of EMLA cream provides equal analgesia to the injection of lidocaine.³⁶ The time required for EMLA cream to work (Chapter 154) is usually not available for deliveries in the Emergency Department.

Alternatively, a bilateral pudendal nerve block will provide excellent pain control (**Figure 163-4B**). It requires more time to perform and cannot be done if the baby's head is in the vagina. Arm a 10 mL syringe with a 23 gauge spinal needle and filled with local anesthetic

FIGURE 163-4. Anesthesia of the perineum. **A.** Local anesthetic infiltration subcutaneously from the posterior fourchette to the anus. **B.** The pudendal nerve block.

solution. Place the nondominant index finger in the vagina and palpate the ischial spine. The ischial spines are identified as the bony protrusions located in the posterolateral region of the vaginal side wall. The sacrospinous ligament is a firm band that runs from the ischial spine to the sacrum. The pudendal nerve and artery lie between the ischial spine and ischial tuberosity. Palpate the ischial tuberosity with the nondominant thumb.

To perform the block on the maternal right side, use the right index and middle fingers to palpate the right ischial spine and guide the spinal needle. Use the left hand to introduce the needle. Insert the tip of the needle two finger breadths medial to the ischial spine (**Figure 163-4B**). Advance the needle through the sacrospinous ligament. Aspirate to ensure that the injection is not intravascular. Inject 3 to 4 mL of local anesthetic solution. Advance the needle a few millimeters, aspirate, and then inject another 3 to 5 mL of local anesthetic solution. Repeat the procedure on the contralateral side. Occasionally, a cutaneous branch of the inferior anal nerve can

innervate the area surrounding the anus. The infiltration of a local anesthetic solution will be required.¹¹

A pudendal nerve block is usually performed intravaginally by the Obstetrician (**Figure 163-4B**). This increases the risk of an Emergency Physician sticking themselves with the needle. It may be easier to perform the block subcutaneously (**Figure 163-4B**). The decision is physician dependent.

TECHNIQUES

MIDLINE EPISIOTOMY

Make the incision vertically in the midline of the perineal body from the midpoint of the posterior vaginal orifice to halfway toward the anus (**Figure 163-5**). The incision length depends upon the perineal length. **Make it of sufficient length to increase the area of the introitus for successful delivery of the presenting part without**

FIGURE 163-5. Performing a midline episiotomy. **A.** Place the nondominant index and middle fingers inside the introitus with the palm facing outward. **B.** Pull the perineal body away from the fetus and insert the straight Mayo scissors. Note that the blades of the Mayo scissors are positioned between the fingers. **C.** The introitus readily opens after making the episiotomy.

compromising the anal sphincter. The incision must include the tendinous central portion of the perineal body. The most important aspect of the midline episiotomy is extension of the incision upward into the vaginal epithelium and past the hymenal ring. This releases any constriction and allows maximal room for the presenting part of the fetus.

Place the index and middle fingers of the nondominant hand into the patient's introitus with the palm of the hand facing outward (Figure 163-5A). Pull the perineal body away from the fetal presenting part to protect the fetus from injury (Figure 163-5B). Use a Mayo scissors to make the incision (Figures 163-5B and 163-5C). A scalpel can cause significant injury to the fetus, the mother, and/or the Emergency Physician.

Insert the Mayo scissors so that one blade lies along the skin and the other is inside the introitus between the index and middle fingers and against the vaginal epithelium (Figure 163-5B). Allow the maximum descent of the fetal presenting part and moderate distension of the perineum before making the incision to avoid a third-degree or fourth-degree laceration. Make the incision when the perineum is bulging and when approximately 4 cm of fetal scalp is visible during a contraction unless early delivery is indicated.^{1,19} Extend the incision 2 to 3 cm vertically up the vaginal epithelium past the hymenal ring. The introitus will readily open after making the episiotomy (Figure 163-5C).

MEDIOLATERAL EPISIOTOMY

Make an incision at a 45° angle to the midline of the posterior vaginal orifice, from the inferior portion of the hymenal ring toward the ischial tuberosity (Figure 163-2B). The angle must be increased to 60° to obtain the correct angle of incision during pushing or distention of the perineum. The length of the incision is less critical than that for a median episiotomy. Longer incisions require a more extensive repair. The side to which the episiotomy is performed is generally the same as the handedness of the operator.¹ Make the incision at approximately 5 o'clock for left-handed dominants or at 7 o'clock for right-handed dominants. If the incision is not deep enough, there will be too little tissue relaxation and a second incision will be necessary. This second incision increases the risk of a zigzag line after healing.¹¹

The anatomic structures incised and requiring repair (in progression from superficial to deep) are the skin and subcutaneous tissues, the bulbospongiosus muscle, the superficial transverse perinei muscle, and a portion of the levator ani muscle and its fascia.

ASSESSMENT

Carefully examine the vagina, cervix, and lower uterine segment for any signs of injury or laceration immediately following delivery of the infant and placenta. Do not begin repairing the episiotomy until after the delivery of the placenta. The repair may be compromised if manual removal of the placenta or intravaginal procedures must be performed after the episiotomy is reconstructed. Assess the incision for extension into a third-degree laceration or fourth-degree laceration with a rectal exam. A rectal exam will also identify a button hole (i.e., a laceration through to the rectal mucosa that is not contiguous with the episiotomy). Identify any site of excessive bleeding and immediately control it with Vicryl suture.

MIDLINE EPISIOTOMY REPAIR TECHNIQUES

A midline episiotomy is easier to repair. The incision is symmetrically situated in the perineal body.^{23,37,38} There are several options for episiotomy closure with limited data to suggest the superiority of one single type of suture material. An absorbable synthetic suture (e.g., polyglactin) is recommended, although they frequently require removal during the puerperium. Vicryl Rapide and absorbable monofilament have gained popularity for repair of episiotomies and perineal lacerations to avoid removal of persistent suture material. The use of chromic gut is associated with the rapid loss of tensile strength, increased wound breakdown, and increased initial pain.²⁶ Adhesive glue can be used for closure of perineal skin to decrease the operative time.³⁹ The traditional repair methods using suture techniques are described below.

ONE-SUTURE REPAIR TECHNIQUE

The one-suture technique uses one strand of suture to close the entire episiotomy. Repair the vaginal mucosa first (Figure 163-6). Use 3–0

FIGURE 163-6. Methods of closing the vaginal mucosa. **A.** The running subcuticular stitch. **B.** The running simple stitch. **C.** The running locked stitch.

FIGURE 163-7. The one-suture technique to close an episiotomy. **A.** Approximate the vaginal mucosa with a running stitch. **B.** Approximate the hymenal ring followed by a running stitch to approximate the perineal body. **C.** Reverse the suture direction with a running subcuticular stitch to approximate the skin.

Vicryl on a noncutting needle. Place the initial suture superior to the apex of the vaginal incision to incorporate any retracted vessels. Tie the suture at the apex of the incision securely. Approximate the wound edges with a running subcuticular stitch (**Figure 163-6A**), a running simple stitch (**Figure 163-6B**), or a running locked stitch (**Figure 163-6C**) if there are any concerns about hemostasis.⁴⁰ Continue the suture to the hymenal ring. Each suture should be of sufficient depth to approximate the vaginal epithelium and underlying muscularis layers to the midline thereby assuring closure of dead space. **The stitch should not be so deep as to cause penetration of the rectal mucosa. Do not allow the needle to enter through the rectal mucosa as this can result in the formation of a rectovaginal fistula.**

This method of suturing provides for hemostasis, eliminates dead space, and decreases the risk of subsequent infection. Once the hymenal ring is reached, throw the next stitch under the hymen exiting from the midline of the perineal body. The crown stitch is next and performed by reapproximating the bulbocavernosus muscles to the midline (**Figure 163-7A**). This is carried down in a running fashion to approximate the remaining superficial muscles of the perineum and subcutaneous fat toward the inferior angle of the episiotomy (**Figure 163-7B**). The repair is completed with a subcuticular closure of the perineal skin to the apex (**Figure 163-7C**). The suture is directed from the midline into the vagina and placed through both sides of vaginal epithelium and tied upon itself ideally behind the hymenal ring.²⁶

TWO-SUTURE REPAIR TECHNIQUE

This technique uses two strands of suture to close the episiotomy (**Figure 163-8**). Close the vaginal mucosa with a running stitch as described previously (**Figure 163-8A**). Approximate the hymenal ring with this first strand of suture (**Figure 163-8B**). Perform the crown stitch and remaining perineal body stitches with single interrupted stitches using a second strand of suture (**Figure 163-8B**). Use the first strand of suture to place a subcuticular running stitch to approximate the skin (**Figure 163-8C**). Finish approximating the skin incision with a buried knot.

ALTERNATIVE TECHNIQUE

Approximation of an episiotomy with one or two sutures can be time consuming and difficult. An alternative is to close the episiotomy using simple interrupted stitches (**Figure 163-9**). Take deep bites of tissue with the needle to ensure that the stitches close the subcutaneous tissues, perineal body, vaginal mucosa, and skin.

EPISIOTOMY EXTENSIONS

During a vaginal delivery, there is a small risk of lacerations extending into the muscular anal sphincter complex and the rectal mucosa, termed third-degree and fourth-degree lacerations, respectively. These lacerations may occur spontaneously or as a direct extension of an episiotomy. Visually inspect the perineum after every delivery and perform a digital rectal examination to assess the integrity of the external anal sphincter and the rectal mucosa. The repair of third-degree and fourth-degree lacerations is described below.

THIRD-DEGREE LACERATION REPAIR

A third-degree laceration involves the anal sphincter muscle and spares the anal mucosa. Visually inspect the anal sphincter muscle for partial lacerations. **A patient can have normal anal sphincter tone and a partial anal sphincter muscle laceration.** Repair any anal sphincter muscle lacerations as described in the following section on fourth-degree laceration repair.

FOURTH-DEGREE LACERATION REPAIR

Fourth-degree lacerations involve the anal sphincter muscle and the anal mucosa. They must be repaired to restore the normal anatomy and decrease the chance of fecal incontinence and a rectovaginal fistula.

A suture is placed 1 cm above the apex of the laceration and extended through the submucosal tissue but not through the rectal mucosa. Close the rectal mucosa in a continuous running or subcuticular fashion. Use a delayed absorbable suture such as 3-0 polyglactin. The suture should not penetrate the rectal mucosa and is

FIGURE 163-8. The two-suture technique to close an episiotomy. **A.** Approximate the vaginal mucosa with a running stitch. **B.** The hymenal ring is approximated with the first suture. The perineal body is approximated with a second suture utilizing an interrupted stitch. **C.** The first suture is continued subcutaneously to approximate the skin.

carried down to the anal verge. Place a second layer of sutures over the rectal mucosa to reinforce the initial sutures. Additionally, this suture will close the dead space between the vaginal mucosa and the rectum.

Identify the internal anal sphincter muscle. This is a thin band of smooth muscle encircling the anal mucosa. It appears whitish in color to the naked eye. Repair it with single interrupted stitches using 3-0 polyglactin or 3-0 polydioxanone suture material.

Identify both ends of the external anal sphincter. They are usually retracted laterally. Use Allis clamps to grasp the edges and pull them together in the midline (**Figure 163-10A**). Repair the sphincter with four single interrupted stitches using 2-0 polyglactin or 3-0 polydioxanone on a tapered needle.⁴¹ **Incorporate the capsule**

of the external anal sphincter in the repair and not just the muscle fibers (Figure 163-10B). The authors recommend the use of the pneumatic “PISA” when repairing the external anal sphincter (**Figure 163-10C**). Initiate the repair with the Posterior aspect of the sphincter which has the structure of a cylinder at the 9 o’clock position. Place the most Inferior suture at the 6 o’clock position. Place a stitch in the Superior aspect at the 12 o’clock position. Finish the repair with a suture at the 3 o’clock position on the Anterior aspect of the sphincter. **Perform a rectal exam after the repair to test for adequate sphincter tone or penetrating suture.**

Alternatively, perform an overlap repair of the external anal sphincter.⁴¹ Mobilize both ends to allow interposition of the ends of the sphincter. This requires a complete transection of the sphincter and expertise with a more extensive dissection of the sphincter. Reserve this type of repair for the Obstetrician.

MEDIOLATERAL EPISIOTOMY REPAIR TECHNIQUE

The mediolateral episiotomy repair requires more surgical skill and anatomic knowledge. Perform the repair of the vaginal epithelium as one would with a midline episiotomy to the level of the hymenal ring. Repair the pelvic floor muscle (i.e., levator ani) with single interrupted stitches using delayed absorbable suture (e.g., 2-0 polyglactin). The medial edge of this muscular layer lies close to the anterior rectum. Care must be taken to avoid passing the needle into the rectum.²⁶

It is extremely important to locate and repair the transected bulbospongiosus muscle. Find and grasp the transected ends of the bulbospongiosus muscle with Allis clamps. The lateral edge of this muscle may have retracted superiorly into the labia majora requiring adequate exposure of the underlying tissue and deep suture placement to ensure successful closure.²⁶ Approximate the bulbospongiosus muscle using single interrupted stitches with 2-0 or 3-0 polyglactin suture (**Figure 163-11A**). Approximate the remaining subcutaneous tissue and perineal skin using the one-suture or the two-suture technique as a midline episiotomy repair (**Figure 163-11B**). Approximate the skin of the perineum using a running subcuticular stitch (**Figure 163-11C**).

FIGURE 163-9. An alternative technique to close an episiotomy. Place simple interrupted stitches to approximate the mucosa, skin, and perineal body.

FIGURE 163-10. Repair of a fourth-degree laceration or episiotomy. **A.** Approximate the rectal submucosa and muscularis with simple interrupted sutures. Grasp the cut edges of the anal sphincter muscle with Allis clamps. **B.** Approximate the ends of the anal sphincter muscle with transfixion stitches. **C.** Repairing the anal sphincter muscle. (A, anterior; I, inferior; P, posterior; S, superior.)

AFTERCARE

The aftercare for a perineal incision involves perineal hygiene and adequate analgesia. Routine use of prophylactic antibiotics has never been proven effective to prevent infections after an episiotomy. A single intravenous dose of a second-generation cephalosporin (e.g., cefazolin) during or immediately after the repair of a third-degree

or fourth-degree laceration is recommended.⁹ The use of warm sitz baths three to four times a day in concert with the use of ice packs to the perineum will decrease inflammation. Prescribe stool softeners to decrease the pain of defecation and the risk of episiotomy disruption, especially if it was associated with a third-degree or fourth-degree extension. Nonsteroidal anti-inflammatory drugs or acetaminophen provides adequate analgesia in most patients.

FIGURE 163-11. Repair of a mediolateral episiotomy. **A.** Find and approximate the ends of the transected bulbospongiosus muscle. **B.** Approximate the vagina and deep perineal tissues using the one-suture or two-suture technique. **C.** Approximate the skin with running subcuticular stitches.

Narcotic analgesics may be required for 24 to 72 hours, especially in cases of mediolateral episiotomies. Many Obstetricians prefer oxycodone or acetaminophen with codeine as they are not as constipating as the other narcotic analgesics. This is especially important in patients with third-degree or fourth-degree lacerations.

COMPLICATIONS

The most common complications are hemorrhage, infection, and dehiscence. Most hemorrhage can be controlled by the application of direct pressure with sterile gauze. Bleeding vessels may be secured with single interrupted stitches or incorporation into the repair using a running locked technique. The mediolateral episiotomy has an increased risk of hemorrhage compared to the midline episiotomy. Adequate hemostasis must be assured during the repair. Vaginal hematomas can easily form. Large or expanding vaginal hematomas usually require the incision to be opened, the hematoma drained, and the hemorrhage controlled. Small hematomas can be managed with analgesics, vaginal packing, and ice packs.

Infection usually presents 6 to 8 days after delivery. The patient usually complains of a fever, perineal pain, and a purulent discharge that may be foul smelling. Management includes local perineal care and exploration with debridement under adequate anesthesia to drain a potential abscess. Carefully examine the patient and explore the area to rule out necrotizing fasciitis.²⁸ Begin intravenous antibiotics after consulting with the Obstetrician-Gynecologist and obtaining wound cultures.

Pain at the episiotomy site is common. It usually resolves in 3 to 5 days. The pain usually responds to acetaminophen and nonsteroidal anti-inflammatory drugs. A hematoma or an infection must be ruled out if the patient is complaining of intense pain. Dyspareunia is more common with a mediolateral episiotomy.¹¹ Prospective studies have not found differences in the resumption of intercourse at 3 months when compared to patients without an episiotomy.⁸ No difference in pain was noted in one study between continuous and interrupted suture closure.⁴⁰ A Cochrane review noted less short-term pain, the decreased need for analgesics, the lack of suture removal, and the use of less suture material with continuous sutures.⁴² The decision to use continuous or interrupted sutures is up to the Emergency Physician and depends on several factors (e.g., time constraints and the ability to place).

Dehiscence is reported in 0.1% to 2% of episiotomies. Early closure within 1 week is preferable to the delayed closure at 2 to 3 months. It is necessary to remove all necrotic tissue and copiously irrigate the area with a diluted povidone iodine solution. This is followed with twice-daily scrubbings of the wound with a scrub brush and povidone iodine. The wound can be repaired once it is free of exudates and begins to show granulation tissue. Intravenous antibiotics might be necessary in the presence of an infection.⁴³ The repair procedure should be performed by a Gynecologist or a Colorectal Surgeon if the dehiscence involves the anal sphincter.

The use of a midline episiotomy may increase the risk of third-degree and fourth-degree lacerations which may result in incontinence of feces, incontinence of flatus and/or rectovaginal fistula formation if not properly repaired.⁴⁴⁻⁴⁷ Use a mediolateral episiotomy for patients at increased risk for third-degree or fourth-degree lacerations (e.g., short perineal body or during forceps delivery).

SUMMARY

Episiotomies should be performed selectively for appropriate indications. Clinical judgment, patient assessment, expertise level, and common sense should be employed. The midline episiotomy is the preferred technique for non-Obstetricians. It is easier to perform and easier to repair when compared to the mediolateral episiotomy. It carries a higher risk for extension into the anal sphincter.

FIGURE 164-1. The head may retract toward the perineum (i.e., turtle sign) when delivery of the fetal head is not followed by delivery of the shoulders.

It has been reported in up to 4% of cephalic spontaneous vaginal deliveries.^{2,7} Differing definitions of shoulder dystocia may account for some of this variability. Some reports require that maneuvers for shoulder release be documented on the chart whereas others accept the clinical diagnosis of shoulder dystocia. Other definitions look at the timing of the delivery of the head in relation to the delivery of the shoulders or the completion of the birth. The rare occurrences of shoulder dystocia make designing prospective studies difficult in describing the incidence and in evaluating the efficacy of various release maneuvers.⁸

Shoulder dystocia is most often unpredictable and unanticipated because accurate methods of predicting do not exist. Risk factors that increase the risk for shoulder dystocia are documented in the literature (**Table 164-1**). Many patients with shoulder dystocia do not have risk factors. Emergency Physicians may not have access to the patient's prenatal history and/or ultrasound reports that may highlight the presence of risk factors for shoulder dystocia. It is therefore imperative for the Emergency Physician to be knowledgeable and comfortable with the various release maneuvers if shoulder dystocia is encountered during a precipitous delivery.⁹

164

Shoulder Dystocia Management

Christopher Freeman and Adi Abramovici

INTRODUCTION

Shoulder dystocia is a rare obstetric emergency placing the mother and the fetus at risk for significant morbidity and mortality. It is diagnosed when after delivery of the fetal head further expulsion of the fetus is prevented by impaction of the fetal shoulders within the maternal pelvis (**Figure 164-1**).¹ **Shoulder dystocia is considered an emergent situation. The Emergency Physician must be able to recognize the condition and quickly respond. The goal is to deliver the fetus as quickly as possible using safe maneuvers and documenting the chain of events.**

The incidence of shoulder dystocia varies due to the subjective nature of the diagnosis and the dependency on the documentation.

TABLE 164-1 The Risk Factors for Shoulder Dystocia

Antepartum	Intrapartum
Abnormal pelvic anatomy	Arrested dilation
Advanced maternal age	Assisted delivery (forceps or vacuum)
Diabetes (actual or gestational)	Descent arrested, failed, or protracted
Excessive weight gain	Labor augmentation (e.g., oxytocin)
Fetal macrosomia	Pelvimetry concerning for cephalopelvic disproportion
Male fetus	Prolonged labor of first stage
Maternal obesity	Prolonged labor of second stage
Multiparity	
Previous large baby	
Previous shoulder dystocia	
Prolonged pregnancy	
Short maternal stature	

ANATOMY AND PATHOPHYSIOLOGY

Shoulder dystocia is usually diagnosed after delivery of the fetal head when the fetal shoulders fail to deliver despite standard gentle traction on the fetal head. It results from impingement of the biacromial diameter of the fetus against the maternal pubic symphysis anteriorly and the maternal sacral promontory posteriorly.¹⁰ Additional definitions are a delivery in which maneuvers are required to deliver the fetus after normal gentle downward traction the head delivers but external rotation does not occur and the head recoils tightly against the perineum (i.e., turtle sign) or a head-to-body delivery completion of greater than 60 seconds.^{11,12} Shoulder dystocia can frighten the Emergency Physician and the patient.

Shoulder dystocia is a rare and potentially catastrophic obstetrical emergency. The Emergency Physician must deliver the fetus quickly and without applying excessive forces that may result in fetal injury. Associated risk factors include fetal macrosomia,

maternal diabetes, multiparity, obesity, operative vaginal delivery, prior history of shoulder dystocia or macrosomia, prolonged second stage of labor, and postterm pregnancy (Table 164-1).¹⁰

Fetal macrosomia is defined as fetal growth beyond a specific weight, usually 4000 to 4500 gm, regardless of the fetal gestational age. The risk of shoulder dystocia is 9.2% to 24% in nondiabetic pregnant women and 19.9% to 50% in diabetic women when birth weight is greater than 4500 gm.¹³ Dystocia can occur unexpectedly in infants of normal birth weights.¹³ A simple algorithm to help determine if shoulder dystocia or fetal macrosomia may be present is shown in Figure 164-2.

INDICATIONS

The presence of shoulder dystocia requires immediate recognition and action. Most cases will respond to commonly used maneuvers. Utilize the maneuvers in the approximate order described in this

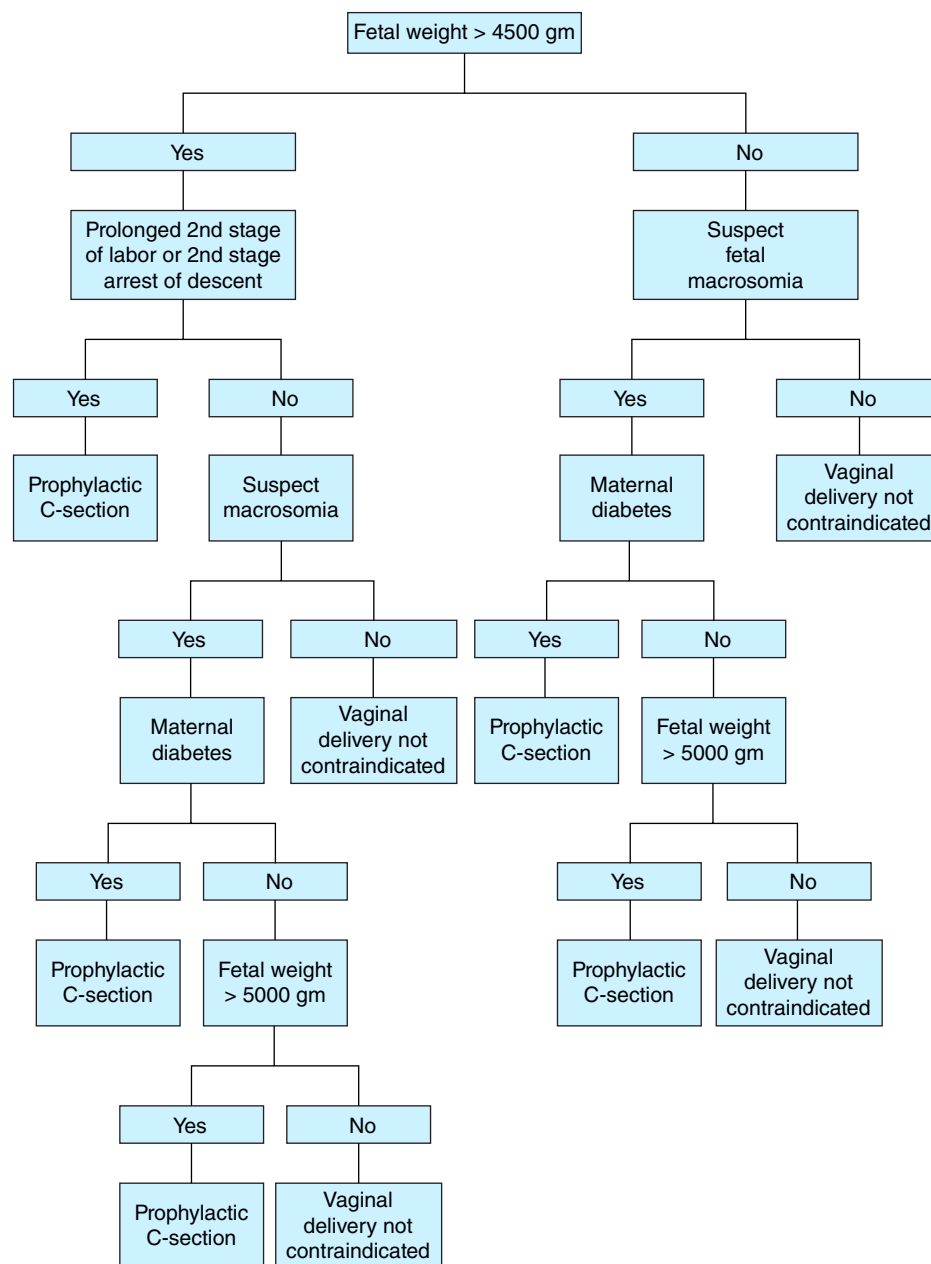

FIGURE 164-2. An algorithm providing a sequence of decisions for evaluation and anticipation of shoulder dystocia.¹³

chapter from the least invasive and easiest to perform to the most invasive and difficult to perform (**Figure 164-3** and **Table 164-2**). More aggressive approaches may be indicated in cases that are refractory to successful delivery of the neonate.

Documenting shoulder dystocia is imperative and the American College of Obstetrics and Gynecology (ACOG) has a standardized checklist to be used in the documentation process if a patient has experienced shoulder dystocia (**Figure 164-3** and **Table 164-2**).¹⁴ Call for help from Anesthesiologists, Neonatologists or Pediatricians, and Neonatal Intensive Care Unit Staff. Assign a timekeeper. Perform the maneuvers. Reevaluate the course of action including using other maneuvers or repeating maneuvers. Consider abdominal delivery (i.e., cesarean section). Document the events using a checklist.

A symphysiotomy (Chapter 168) is indicated for shoulder dystocia unresponsive to less invasive techniques and for fetal head entrapment by presumed cephalopelvic disproportion. It is an

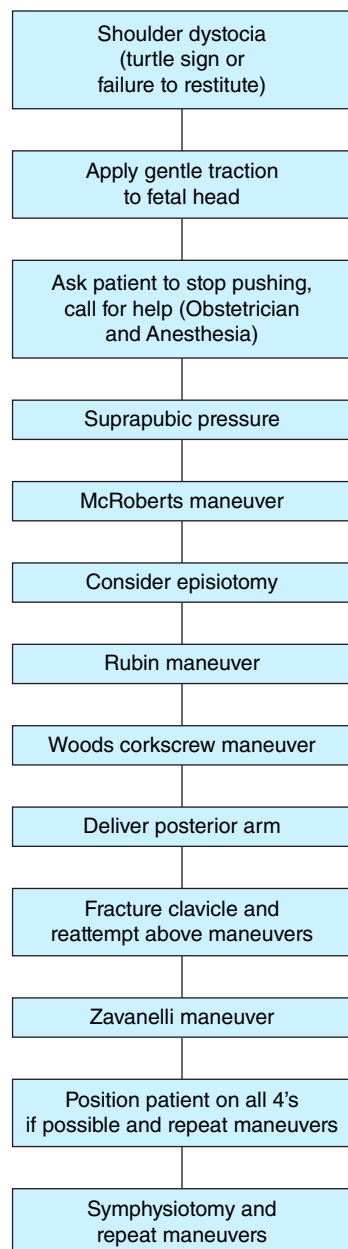

FIGURE 164-3. Algorithm for the treatment of shoulder dystocia. Perform in the order listed from least to most invasive.

TABLE 164-2 Common Mnemonics for the Treatment of Shoulder Dystocia

ALARMER

A – Ask for help
L – Lift and hyperflex legs (McRoberts maneuver)
A – Anterior shoulder disimpaction
R – Rotation
M – Manually remove posterior arm
E – Episiotomy
R – Roll over onto all fours

BE CALM

B – Breathe and stop pushing
E – Elevate the legs into McRoberts maneuver
C – Call for help
A – Apply suprapubic pressure and not fundal pressure
L – Enlarge the vaginal opening (i.e., episiotomy)
M – Maneuvers to deliver posterior arm or rotational maneuvers

HELPERR

H – Help (call for assistance)
E – Evaluate for episiotomy
L – Legs (McRoberts position)
P – Pressure (apply suprapubic pressure)
E – Enter maneuvers (perform rotational maneuvers)
R – Remove the posterior arm
R – Roll the patient onto all fours

alternative to the cesarean section when a qualified Obstetrician or Surgeon is unavailable.¹³

CONTRAINDICATIONS

The only absolute contraindication is if the procedure might endanger the mother. Consider an emergency cesarean section if an Obstetrician is available when shoulder dystocia is of high clinical concern prior to fetal crowning (**Figure 164-2**). The Emergency Physician is usually only managing precipitous deliveries where there is no other personnel trained in the management of laboring patients.

The indications to perform a cesarean delivery are relative contraindications for release maneuvers. ACOG supported the recommendation that planned cesarean delivery may be a reasonable strategy for diabetic pregnant women with estimated fetal weights exceeding 4250 to 4500 gm (**Figure 164-2**).⁸ ACOG issued guidelines on fetal macrosomia in 2001.⁸ The guidelines were based upon limited or inconsistent scientific evidence. ACOG recommended that an estimated fetal weight of more than 4500 gm, a prolonged second stage of labor, or arrest of descent in the second stage of labor are indications for cesarean delivery.^{8,13} ACOG noted that the diagnosis of fetal macrosomia is imprecise and recommended prophylactic cesarean delivery be considered with estimated fetal weights of more than 5000 gm in nondiabetic pregnant women and more than 4500 gm in diabetic pregnant women.¹³

EQUIPMENT

GENERAL SUPPLIES

- Electronic fetal monitor
- Sterile towels
- Clock or timer watch
- Sterile perineal drapes
- Sterile gloves

- Chromic suture, 2-0 and 4-0
- Vicryl suture, 2-0 and 3-0
- Bulb syringe
- Clean towels/blanket for baby
- Umbilical cord clamp
- Sterile scissors
- Infant warmer
- Step stool to be placed next to the patient's bedside
- Neonatal resuscitation equipment and medications

■ DELIVERY INSTRUMENT PACK

- Sterile bandage scissors
- Towel clips
- 2 Allis forceps
- 4 ring forceps
- 6 straight Kocher clamps
- Straight Mayo scissors
- 2 suture scissors
- Adson forceps, or other forceps with teeth
- Russian forceps, 5½ inches and 8 inches
- Gelpi retractor
- Richardson retractors, small and medium
- Army-Navy retractors
- 6 inch needle driver

■ SYMPHYSIOTOMY

- #10 or #15 scalpel blade on a handle
- Finger guard
- Foley catheter
- Povidone iodine or chlorhexidine solution

PATIENT PREPARATION

Explain the risks, benefits, and alternative procedures to the patient and/or their representative. Include fetal distress, fetal death, fetal hypoxia, and hysterectomy in the discussion. Obtain an informed consent for the procedure and place this in the medical record. There is often not enough time to obtain a written consent in the Emergency Department. Carefully and completely document this discussion in the medical record.

Pain associated with the first stage of labor can be relieved with a paracervical block or pudendal nerve block.¹⁵ Inject 5 mL of local anesthetic solution into the submucosa of the lateral vaginal fornix. Repeat the injection in the contralateral lateral vaginal fornix. Pain transmission is interrupted for all visceral sensory nerve fibers from the cervix, upper vagina, and uterus. The somatosensory fibers from the perineum are not blocked. This technique is effective only during the first stage of labor and before shoulder dystocia occurs.^{15,16} **These anesthetic techniques must be performed prior to the occurrence of shoulder dystocia.**

Place the patient in the lithotomy position on a bed with stirrups. Preparation begins with recognition of fetal macrosomia by clinical examination or fetal ultrasound. Retraction of the fetal head immediately after its delivery and the fetal chin against the maternal thigh (i.e., turtle sign) with difficulty delivering the anterior shoulder signals the beginning of action toward resolving the shoulder dystocia (Figure 164-1).

FIGURE 164-4. Restitution (i.e., external rotation) of the fetal head normally results in a natural perpendicular relationship of the head to the shoulders.

The fetal sagittal suture generally lies oblique to the maternal anteroposterior diameter with the fetal shoulders occupying the opposite oblique diameter after delivery of the fetal head (Figure 164-4). The shoulder may become impacted behind the pubic symphysis and impede delivery if the anterior shoulder descends in the anteroposterior diameter (Figure 164-1). Apply gentle and downward pressure on the fetal head to move the posterior shoulder into the hollow of the sacrum and deliver the anterior shoulder (Figure 164-5). **Resist applying excessive downward or lateral traction on the fetal head and neck.**

TECHNIQUES

Perform attempts at gentle traction coordinated with maternal expulsive efforts before attempting maneuvers to relieve shoulder dystocia. Initiate a planned sequence of events if delivery is impeded (Figure 164-3). **Avoid applying fundal pressure and discontinue maternal pushing efforts until disimpaction has occurred.** Fundal pressure and maternal pushing may further impact the fetal shoulders, increase the risk of uterine rupture, and should never be performed. Notify the medical personal in the room of the situation and summon extra personnel for help with one person designated as a time-keeper. Notify a Neonatologist of the impending delivery and contact an Anesthesiologist for pain control. Maneuvers for shoulder dystocia disimpaction will be described in order of ease of implementation and from least invasive to more invasive (Figure 164-3).

FIGURE 164-5. Apply gentle and downward pressure on the fetal head (1) to move the posterior shoulder into the hollow of the sacrum (2) and deliver the anterior shoulder (3).

FIGURE 164-6. Moderate suprapubic pressure is applied to disimpact the fetal shoulder while gentle downward traction is applied to the fetal head.

There is no indication that any one of the described techniques is superior to another to relieve the shoulder dystocia. The use of these techniques should relieve the dystocia. The use of uterine relaxant medications may be necessary to overcome the expulsive forces of the uterine contraction.

SUPRAPUBIC PRESSURE

Use suprapubic pressure alone or in combination with the McRoberts maneuver. Apply gentle downward traction to the fetal head while an assistant simultaneously applies moderate suprapubic pressure with the heel of their hand. The suprapubic pressure can disengage the anterior shoulder from the pubic symphysis. Use a step stool placed on the side of the patient's bed for easier application of suprapubic pressure (**Figure 164-6**). **Do not apply heavy pressure**

to prevent injury to the fetus's brachial plexus, neck, and spinal cord. Start with continuous pressure. Use a rocking motion of pressure to dislodge the anterior shoulder if continuous pressure does not release the shoulder.

McROBERTS MANEUVER

The McRoberts maneuver is easy to perform and has proven to be effective (**Figure 164-7**). It should be used after suprapubic pressure to try to relieve the shoulder dystocia. Place an assistant on each side of the patient. Hyperflex and abduct the mother's thighs onto her abdomen (**Figure 164-7A**). Instruct the assistants to maintain support of the hyperflexion while simultaneously applying suprapubic pressure (**Figure 164-7B**). This results in a flattening of the maternal lumbosacral curve and a rotation of the pubic symphysis cephalad (**Figure 164-7C**). The suprapubic pressure disengages the anterior shoulder from the pubic symphysis. Rotation of the maternal pelvis may free the impacted anterior fetal shoulder.^{7,17} This maneuver has the advantages of reducing shoulder extraction forces, brachial plexus stretching, and the incidence of clavicular fractures.^{7,17} **The McRoberts maneuver is effective in disimpacting the fetal shoulders in 50% to 90% of cases of shoulder dystocia and should be a first-line treatment.**^{7,17-19}

EPISIOTOMY

Episiotomy is a surgical incision at the time of delivery to increase the diameter of the maternal soft tissue of the pelvis and facilitate vaginal delivery (Chapter 163). Consider performing an episiotomy in shoulder dystocia patients when it has not resolved with suprapubic pressure and the McRoberts maneuver. The episiotomy creates extra space for the Emergency Physician's hand. **An episiotomy will not disimpact the anterior shoulder and relieve shoulder dystocia but does allow for increased access of rotational maneuvers.**

The two most commonly used episiotomies are median and mediolateral. The median (i.e., midline) is the easier to perform but is associated with an increased risk of extension toward the anal

FIGURE 164-7. The McRoberts maneuver. **A.** Hyperflex the maternal thighs upon the abdomen. **B.** An assistant applies suprapubic pressure while maintaining flexion of the legs. **C.** This maneuver results in cephalad rotation of the maternal pelvis and an increase in the size of the pelvic outlet.

FIGURE 164-8. The Rubin maneuver. Rotation of the anterior shoulder counterclockwise through a small arc to the oblique position.

sphincter (i.e., third-degree tear) and rectum (i.e., fourth-degree tear). The mediolateral episiotomy has a decreased risk of extension but is less commonly used because it can be more difficult to repair, increases the risk of bleeding, and causes more postpartum discomfort.²⁰

RUBIN MANEUVER

The Rubin maneuver is simple and may lead to the descent and delivery of the anterior fetal shoulder (Figure 164-8). Insert the dominant hand into the vagina. Place the fingers of the hand against the posterior aspect of the anterior fetal shoulder. Rotate the fetal shoulder in a small arc toward the fetal chest. **The Rubin maneuver compresses and diminishes the size of the fetal shoulder girdle to disimpact the anterior shoulder.** Rotation of the anterior fetal shoulder in the opposite direction (i.e., toward fetal back) will open the shoulder girdle, increase the size of the shoulder girdle, and further impact the fetus.

WOODS CORKSCREW MANEUVER

The Woods corkscrew maneuver (Figure 164-9) is an alternative to the Rubin maneuver and is the release of the posterior shoulder. Insert the dominant hand into the vagina. Place the fingers of the hand against the posterior aspect of the posterior fetal shoulder. Gently rotate the posterior shoulder toward the chest (Figure 164-9).²¹ **This maneuver compresses and diminishes the size of the fetal shoulder**

FIGURE 164-9. The Woods corkscrew maneuver. Rotation of the posterior shoulder through a 180° arc.

girdle to disimpact the anterior shoulder. Rotation in the opposite direction (i.e., toward fetal back) will open the shoulder girdle, increase the size of the shoulder girdle, and further impact the fetus.

DELIVERY OF THE POSTERIOR ARM

Delivery of the posterior arm is also known as the Barnum maneuver or Jacquemier maneuver. Attempt to deliver the posterior arm if the previous maneuvers are unsuccessful (Figure 164-10). Insert the dominant hand into the vagina. Place the fingers of the hand against the posterior fetal humerus (Figure 164-10A). Sweep the fetal arm across the chest (Figure 164-10B). Palpate for and grasp the fetal hand (Figure 164-10C). Gently pull the hand along the side of the face. Continue to gently pull the hand to deliver the posterior arm and shoulder (Figure 164-10D). Apply gentle downward traction on the fetal head and arm while an assistant simultaneously applies suprapubic pressure to release and deliver the anterior shoulder (Figure 164-10E). **Do not pull directly on the fetal arm.** Rotate the shoulder girdle into the oblique diameter if traction on the fetal head and arm does not deliver the anterior shoulder.¹⁰ This will usually disimpact the anterior shoulder and allow it to be delivered. **The major disadvantage of this maneuver is that it may result in a clavicle fracture or a humerus fracture.**

DELIBERATE FRACTURE OF THE CLAVICLE

Fracture the fetal clavicle by pressing the anterior clavicle against the maternal pubic symphysis if the above maneuvers fail. This will decrease the rigidity and the size of the fetal shoulder girdle. Exert the pressure in a direction away from the lungs to avoid a pneumothorax. **Never use an instrument to fracture the clavicle.** The instrument may penetrate the thoracic cavity and cause a pneumothorax or result in subsequent osteomyelitis if the skin is punctured.²² The fracture will heal quickly and is much less serious than asphyxia, a brachial plexus injury, or death. This maneuver is difficult to perform.²¹ **It is physically and mentally difficult to deliberately fracture the clavicle of an infant.**

ZAVANELLI MANEUVER

The Zavanelli maneuver involves replacement of the fetal head followed by a cesarean section (Figure 164-11). Use this maneuver when other maneuvers fail or as a last resort. This procedure is reserved for catastrophic situations due to the increased risk of perinatal and maternal morbidity and mortality. Consider using uterine relaxant medications to stop the uterine contractions. **The expelled head must undergo two maneuvers to reverse the mechanisms of labor.** Manually rotate the fetal head into the pre-restitution position (Figure 164-11A). This is usually the direct occiput anterior position with full extension of the neck (Figure 164-11B). The second maneuver is flexion of the fetal head followed by gentle upward pressure on the head to replace it into the maternal vagina (Figure 164-11B).

The Emergency Physician must maintain their hand in the vagina and maintain gentle pressure on the fetal head to prevent re-expulsion. Keep the hand in the vagina and hold the fetal head during the entire transport to the Operating Room and until a cesarean section is performed. The Emergency Physician can quickly switch their hand with that of an assistant at any time.

This series of maneuvers decompresses the fetus. Immediately transport the mother to the Operating Room for a cesarean section. The Zavanelli maneuver was found to be successful in 84% of initial attempts and 91% of attempts when uterine-relaxing anesthesia or uterine-relaxing medication (e.g., usually 0.25 mg terbutaline subcutaneously) was administered.^{23,24} It was successful on the first attempt by untrained practitioners in 69% of the cases.

FIGURE 164-10. Delivery of the posterior arm. **A.** Insert a hand into the vagina and along the posterior fetal humerus. **B.** Sweep the fetal arm across the chest. **C.** Grasp the hand and extend the arm along the side of the face. **D.** Deliver the posterior arm and shoulder from the vagina. **E.** Apply gentle downward traction on the fetal head and arm while an assistant simultaneously applies suprapubic pressure to deliver the anterior shoulder.

GASKIN MANEUVER

The Gaskin maneuver is also known as the “all-fours” maneuver and named after the midwife Ina May Gaskin (**Figure 164-12**). It is old and not familiar to many. It is considered an effective, rapid,

and safe technique to relieve a shoulder dystocia.²⁵ This increases the pelvic diameters and allows better access to the posterior shoulder. Roll the patient prone then have her get up on all four extremities (**Figure 164-12**). Use gentle downward traction to deliver the

FIGURE 164-11. The Zavanelli maneuver. **A.** Manually return the fetal head to the pre-restitution position if restitution has occurred. This position is usually the direct occiput anterior position. **B.** Flex the fetal head and apply gentle upward pressure to place the fetal head back into the vagina.

FIGURE 164-12. The Gaskin or all-fours maneuver.

posterior shoulder with the help of gravity. Reattempt the above maneuvers in this position if the shoulder dystocia is not relieved. There are problems associated with this position. It may disorient the Emergency Physician while performing the maneuvers and the posterior shoulder is delivered first. Traction is still applied toward the floor but to deliver the posterior shoulder. The position is difficult to maintain in the exhausted patient.

SYMPHYSIOTOMY

A symphysiotomy is an uncommon procedure and a last effort used primarily in two situations (Chapter 168). The first is shoulder dystocia unresponsive to less invasive techniques. The second is when the head of a breech delivery is trapped by presumed cephalopelvic disproportion. It serves as an alternative to the more invasive cesarean section. It is especially useful in situations where an Obstetrician or Surgeon is unavailable.²⁶

ASSESSMENT

Hand the infant to others to resuscitate if a Neonatologist or Neonatal Nurse is present so the Emergency Physician can attend to the mother. Let a Gynecologist attend to the mother while the Emergency Physician attends to the infant if a Neonatologist is not available. Resuscitate both patients as necessary. Determine if the mother has any hemorrhage and deliver the placenta.

AFTERCARE

Disimpaction of the shoulder girdle is usually followed by delivery of the infant. Clamp and cut the umbilical cord. Immediately assess and implement any resuscitative measures for the infant without delay. Deliver the placenta. Repair any lacerations, Dührssen's incisions, episiotomy incisions, perineal lacerations, and vaginal lacerations. Refer to Chapter 163 for the complete details regarding episiotomy repair. Refer to Chapter 166 for the complete details regarding postpartum hemorrhage management. Initiate uterine massage and administer Pitocin following delivery of the placenta to prevent postpartum hemorrhage. Accurately, clearly, and completely document the series of events in the medical record. **Do this for good medical management and in case the infant has complications and the family litigates.** Standard forms provide consistent and complete documentation.¹⁴ Make sure the documentation includes all personnel present, fetal head position, sequence of maneuvers and any complications from them, the time spent with each maneuver, the time between delivery of the

TABLE 164-3 The Complications Associated with Shoulder Dystocia and the Maneuvers to Relieve It	
Fetal	Maternal
Brachial plexus injury	Episiotomy tears
Cerebral palsy	Femoral neuropathy
Clavicle fracture	Lacerations
Death	Postpartum hemorrhage
Humeral fracture	Pubic symphysis separation
Hypoxia	Rectovaginal fistula

head and body, resuscitation required and what was used, and the condition of both patients. Include which shoulder was impacted against the pubic symphysis and infant arm movement after delivery in case nerve palsy develops. Avoid the terms mild, moderate, and severe shoulder dystocia. They offer little information and all refer to shoulder dystocia requiring relief. Notify risk management of the issue and delivery. Review the events with the family, explain any nerve palsy present or possible, and answer any questions.

COMPLICATIONS

Complications can occur for the mother and the fetus from shoulder dystocia (Table 164-3).²⁷ The most common maternal complications are lower genital tract lacerations, postpartum hemorrhage (e.g., secondary to uterine atony or lacerations), and infection.^{2,28} Significant fetal morbidity and mortality are attributable to asphyxia from delayed delivery or trauma sustained during delivery.¹⁰ Perinatal mortality ranges from 2% to 29% in shoulder dystocia. Neonatal morbidity is immediately apparent in 20% of the affected infants.² Neonatal trauma may occur in utero secondary to chronic nerve compression from malposition and during the delivery.¹⁰ Birth trauma occurring during shoulder dystocia may include brachial plexus injuries or Erb palsy (6% to 16%), Klumpke palsy, clavicular fractures (5% to 13%), or humeral fractures.^{3,5,6,21,22,28,29} Many palsies resolve within 6 to 12 months.

SUMMARY

The successful management of shoulder dystocia requires considerable judgment by the Emergency Physician in a timely fashion. Warning signals (e.g., fetal macrosomia based on clinical estimate, maternal diabetes, and labor disorders) should alert the Emergency Physician to be prepared for possible shoulder dystocia. Any of the maneuvers described will usually resolve shoulder dystocia if performed in a methodical fashion. Begin with the simplest and least invasive maneuver and work toward the more invasive maneuvers. Reduction of the time interval from delivery of the head to delivery of the body is crucial to fetal survival.

Breech Delivery

Sarah Christian-Kopp

INTRODUCTION

The breech presentation exists when the cephalic pole of the fetus is positioned in a longitudinal lie and the buttocks or feet of the fetus enter the maternal pelvis before the head.¹ Management of the breech presentation in labor is an area of much trepidation and controversy, even among seasoned clinicians. **A breech delivery is considered a high-risk obstetric complication that is best handled by an Obstetrician.** There are unavoidable situations when a pregnant

woman will present to the Emergency Department in active labor with a fetus in the breech position.²

A vaginal breech delivery may be the best delivery option in situations such as advanced labor with imminent delivery, the absence of obstetrical assistance, fetal distress, or umbilical cord prolapse. **Knowledge and preparedness facilitate comfort and promote success in approaching emergent procedures.** The breech delivery is no exception to this rule.

ANATOMY AND PATHOPHYSIOLOGY

The breech presentation may be associated with a variety of maternal and fetal conditions.^{1,3,4} Maternal variants that increase the risk of a breech presentation include a small pelvis and uterine anomalies (e.g., bicornuate or septate uterus and uterine fibroids). Fetal conditions associated with a breech presentation include fetal malformations (e.g., hydrocephalus, anencephaly, and fetal masses), genetic abnormalities, low birth weight, neurologic disorders, oligohydramnios, prematurity, and polyhydramnios. Other associated factors include multiparity, multiple gestations, placental abnormalities (e.g., placenta previa), and previous breech presentations.

Prematurity is a risk factor for a breech presentation. The incidence of breech presentations is inversely related to the fetal gestational age.^{1,3} Approximately 24% of fetuses are in the breech presentation at 28 weeks of gestation. The fetus usually turns spontaneously to a cephalic presentation so that at term only 3% to 4% are in the breech presentation.^{1,3,5}

There are three main types of breech presentation (**Figure 165-1**).^{4,5} The most common is the frank breech which accounts for 50% to 73% of breech presentations. The fetus is flexed at the hips and extended at the knees (**Figure 165-1A**). The fetus is in the “pike” position. The complete breech is the least common type and accounts for approximately 5% to 11% of breech presentations. The fetus is flexed at both the hips and the knees (**Figure 165-1B**). The footling or incomplete breech accounts for approximately 12% to 38% of breech presentations. The fetus is not completely flexed at one or both knees or hips (**Figure 165-1C**). This results in one or both feet presenting before the buttocks. The risks of umbilical cord prolapse and prematurity associated with the breech presentation are listed in **Table 165-1**.

A breech presentation may be suspected upon clinical examination. The abdominal examination may reveal the hardness of the fetal head palpable in the fundus rather than above the pelvic inlet. A vaginal examination can confirm this suspicion. An ultrasound examination is recommended to confirm presentation when a breech presentation in labor is suspected and can exclude a fetal abnormality when time permits.¹

Breech delivery is divided into three categories. These include unassisted or spontaneous expulsion, partial breech extraction, and total breech extraction.⁶ Unassisted or spontaneous expulsion of the fetus occurs when there is no assistance from the provider in the delivery of the infant. This generally occurs only with very premature infants or in precipitous deliveries where the baby delivers so rapidly as not to allow the provider time to arrive.

Partial breech extraction is spontaneous delivery of the infant to the level of the umbilicus followed by assistance from the provider. This is the usual manner of breech delivery. **Allowing the fetus to descend naturally into the pelvis avoids deflexion of the fetal head, decreases the incidence of head entrapment, decreases the incidence of nuchal arms, and decreases the incidence of umbilical cord prolapse. This is the preferred method of delivery for the Emergency Physician confronted with an actively laboring breech presentation and little hope of obtaining an Obstetrician before delivery.**

FIGURE 165-1. The main types of breech presentations. **A.** The frank breech. **B.** The complete breech. **C.** The incomplete breech.

Total breech extraction occurs when the provider reaches into the uterus and pulls or extracts the fetal feet into the vagina and through the vulva followed by the assisted delivery of the remainder of the infant. Total breech extraction is indicated when expedient delivery is preferred in the absence of an experienced Obstetrician to perform a cesarean section and if performed for the breech presentation of a second twin, acute and profound fetal distress, and/or umbilical cord prolapse.³

The breech presentation has been associated with an increased risk of cerebral palsy and perinatal mortality regardless of the mode of delivery. Failure to adopt the cephalic presentation may in some cases be a marker for preexisting fetal impairment or a result of fetal distress during the birthing process.⁷ The cesarean section has been suggested as the way to reduce perinatal problems associated with the breech presentation.⁸ Cesarean section has become the normal mode of breech delivery in many European countries and in North America. The rate of cesarean section for the breech presentation in the United States has increased from 12% in 1970 to 87% in 2002.⁹ Prospective and retrospective outcome studies over the past several decades have disagreed with this practice.¹⁰⁻¹³

The American College of Obstetricians and Gynecologists (ACOG) recommends that the decision regarding the mode of delivery should be based on the experience of the provider. It is recognized that cesarean delivery will be the preferred mode of delivery. The Term Breech Trial in 2000 compared planned cesarean deliveries with planned vaginal deliveries.¹⁴ It noted that neonatal mortality, perinatal mortality, and serious neonatal morbidity were significantly lower among the planned cesarean delivery group compared with the planned vaginal delivery group. There are circumstances in which a vaginal breech delivery will be preferable (e.g., an obstetric indication, patient preference, or a precipitous delivery).¹⁴

Obstetricians will often perform external cephalic version prior to the delivery date if a breech presentation is identified during prenatal visits.^{1,3,13} **This technique is reserved for the experienced**

Obstetrician as it can be associated with significant complications. External cephalic version cannot be performed if the mother is in active labor and the fetus is engaged in the maternal pelvis.

INDICATIONS

Vaginal breech delivery by the Emergency Physician is indicated when the mother is in active labor and an Obstetrician is not available to perform the delivery or a cesarean section.

CONTRAINDICATIONS

There are no agreed upon absolute contraindications to a vaginal breech delivery. Recommendations have been made based upon factors that increase morbidity and mortality in vaginal and cesarean breech deliveries.^{1,3,6,11} Maternal risk factors for increased morbidity and mortality with a vaginal breech delivery include arrest of labor, pelvic anomalies, a small pelvis, uterine malformations, and uterine masses. Fetal risk factors for increased morbidity and mortality with a vaginal breech delivery include extremes of fetal weight, fetal head extension, prematurity, non-frank breech, and a nonreassuring fetal heart rate pattern.

There are factors regarded as unfavorable for a vaginal breech birth.¹⁵⁻¹⁷ Contraindications include arrest of active labor, a clinically inadequate maternal pelvis, a compromised fetal condition, and placenta previa. Do not vaginally deliver large infants (i.e., larger than 4000 gm) and low birth weight infants (i.e., smaller than 2500 gm) in the breech position. The footling breech presentation can result in more complications than other breech presentations when delivered vaginally. A hyperextended fetal neck makes delivery more complicated and risks injury to the fetus. Do not vaginally deliver a breech fetus unless necessary if inexperienced with the breech delivery technique.

Many of these conditions are not known in an emergent breech presentation. The Emergency Physician may not have the time or experience to assess these conditions. Emergent cesarean delivery is indicated if any of the conditions listed above are known and the setting permits it.

The normal progress of labor with breech presentations has not been extensively evaluated. Poor progress in the active phase of labor may be a sign of fetopelvic disproportion. Failure of the breech to descend once the cervix is completely dilated should be managed with a cesarean section.¹⁵⁻¹⁷

- Povidone iodine or chlorhexidine solution
- Electronic fetal monitor
- Delivery instrument pack (Chapter 162)
- Piper forceps
- Towels
- Clock or timer watch
- Sterile gowns and gloves
- Chromic or Vicryl suture, 2-0 or 3-0
- Richardson or right-angle retractors
- Ring forceps
- Straight Mayo scissors
- Umbilical cord clamps
- 8 inch needle driver
- Sterile drapes

PERSONNEL

- Two medical practitioners if available
- Nursing personnel
- Timekeeper
- Anesthesiologist or Anesthetist if available
- Pediatric or neonatal team if available

PATIENT PREPARATION

Explain the risks, benefits, and alternative procedures to the patient and/or their representative. Obtain a verbal informed consent for the procedure and document this in the medical record. Perform an abdominal and vaginal examination to assess the fetal position.⁵ Apply a fetal monitor and tocodynamometer to the maternal abdomen. Perform ultrasonography if available to confirm the fetal position, to estimate fetal weight, and to evaluate for any gross fetal anomalies.

Epidural anesthesia or a spinal block by an Anesthesiologist is recommended if available and time permits. A pudendal nerve block with local perineal infiltration may be used as an alternative (Chapter 163). Place the mother in the lithotomy position. Scrub the perineum with povidone iodine solution, chlorhexidine solution, or antibacterial soap. Apply a mask with eye protection or goggles, a sterile gown, and sterile gloves. Apply sterile drapes to isolate the patient's perineum (Figure 162-10).

ASSISTED FRANK BREECH DELIVERY

This method is appropriate for all breech presentations. The fetus enters the maternal pelvis with the bitrochanteric diameter in an oblique position (Figure 165-2A). The sacrum is the point of designation for these presentations. The fetus rotates with labor and descent so that the bitrochanteric diameter is in the anteroposterior axis and the sacrum is in the transverse axis (Figure 165-2B).

Encourage maternal "pushing" to expel the fetal buttocks (Figure 165-3A). Support the fetal buttocks with a towed hand. **Do not assist with the delivery of the buttocks as they emerge (Figure 165-3B). Allow the fetus to deliver spontaneously to the level of the umbilicus with only maternal uterine propulsive efforts.** Early extraction of the buttocks increases the risk of head entrapment in a partially dilated cervix, results in deflexion of the fetal head, and increases the risk of nuchal arm entrapment. Perform

a midline episiotomy when the buttocks crown (Chapter 163). **Do not perform the episiotomy too early. This may lead to excessive maternal blood loss.**

Proceed with the delivery of the fetal legs when the umbilicus emerges (Figure 165-4). The legs will likely have delivered themselves by this time if the fetus is in the complete or incomplete breech position. Insert the fingers of the dominant hand along the long axis of the medial fetal thigh (Figure 165-4A). Apply laterally directed pressure on the fetal thigh to flex the knee and externally rotate the leg out and down through the vulva (Figure 165-4A). Apply simultaneous opposite rotation on the fetal hip and pelvis. Deliver the other leg in a similar manner (Figure 165-4B). **Rotation of the hip in a direction opposite the direction of knee flexion facilitates the delivery of the distal extremities. Therefore, rotate the left leg clockwise and the right leg counterclockwise.**

Prepare to deliver the fetal arms (Figure 165-5). Place a sterile towel around the legs and trunk of the fetus for support (Figure 165-5A). Continue to support the fetal body and encourage maternal pushing efforts. **Do not actively assist in the delivery until the fetal scapulae are visible. Aggressive extraction of the fetus following the delivery of the legs may cause deflexion of the vertex or nuchal entrapment of the arms.**

Proceed with active delivery of the shoulders and arms as the scapulae emerge from the vagina (Figure 165-5). Rotate the fetal trunk to present the anterior arm and shoulder (Figure 165-5A). Insert the fingers of the dominant hand longitudinally along the humerus of the presenting arm (Figure 165-5A). Apply traction to the humerus to flex the elbow. Sweep the arm across the chest and deliver it through the mother's vulva (Figure 165-5B). Rotate the fetus in a manner to bring the alternate shoulder into the anterior position (Figure 165-5C). Gently rotate the fetus clockwise to deliver the left arm and counterclockwise to deliver the right arm. This direction of motion prevents the arm from becoming entrapped on the neck. Repeat the procedure to deliver the second arm.

The fetal shoulders and arms may not easily deliver using the above technique. Perform this alternate technique if the arms and shoulders do not deliver. Place the thumbs of both hands over the fetal posterior iliac spines and sacroiliac area. Place the palms and fingers over the fetal hips. **Apply pressure only over the iliac spines. Never grasp the fetal abdomen. The adrenal glands, kidney, liver, and spleen may be injured with excessive pressure during the delivery process.** Elevate the fetal body to deliver the posterior shoulder over the more pliable posterior perineum. Deliver the posterior arm as described above. Lower the fetal trunk. Deliver the anterior shoulder from under the maternal pubic symphysis as described above.

The fetal vertex will generally rotate into the anteroposterior orientation after delivery of the arms and shoulders. The fetal vertex will lie against the maternal pubic symphysis. The fetal chin will lie in the posterior aspect of the vagina and/or lower uterine segment. Wrap the fetal arms and trunk in a towel. Encourage maternal pushing efforts. The fetal head may deliver spontaneously. Note when the fetal chin and mouth appear at the posterior perineum. **Instruct the mother to stop pushing.** Suction the fetal mouth. Gently lift the infant upward to deliver the head in a controlled manner (Figure 165-6). **Avoid hyperextending the fetal back.**

Complete the delivery of the infant. Clamp and cut the umbilical cord. Place the infant in the warmer for examination and resuscitation. The Apgar scores for infants delivered from a breech position are generally slightly lower than from a vertex delivery. The infant may show some initial signs of short-term and generally clinically insignificant hypoxia.

FIGURE 165-2. Breech engagement of the maternal pelvis. **A.** The bitrochanteric diameter is aligned with one of the diagonal diameters. **B.** Descent causes the bitrochanteric diameter to rotate into the anteroposterior axis and the sacrum to rotate into the transverse axis.

FIGURE 165-3. Delivery of the buttocks. **A.** Uterine contractions result in spontaneous emergence of the buttocks while maintaining cephalic flexion. **B.** Premature traction can result in deflexion of the vertex, head entrapment, or nuchal arms.

FIGURE 165-4. Delivery of the legs. **A.** Apply laterally directed pressure on the medial thigh with opposite rotation of the pelvis to deliver the leg. **B.** Repeat the procedure to deliver the other leg.

DELIVERY OF THE FETAL HEAD

Cervical entrapment (i.e., inadequate cervical dilation) is a more common occurrence in the delivery of a fetus in the breech presentation. It is most frequently observed when rapid labor results in the fetal trunk being delivered through a partially dilated cervix or during the delivery of a premature breech when the fetal head is relatively larger than the fetal trunk.

The fetal head often delivers spontaneously with maternal pushing efforts but may occasionally fail to do so. Several options exist to aid in the delivery of the fetal head. These include manual extraction, manual extraction with the McRoberts maneuver or the Mauriceau-Smellie-Viet maneuver, forceps-assisted delivery, and Dührssen's incisions.

Adequate anesthesia is vital to the extraction of the fetal head. A pudendal block and peroneal infiltration should have been performed previously. If not, consider the administration of parenteral sedation and analgesia (Chapter 159) and local infiltration. Inhaled halogenated agents, intravenous beta-mimetics (i.e., terbutaline or ritodrine), and intravenous nitroglycerin are all useful for uterine relaxation in the event of entrapment of the fetal head or if intra-uterine manipulation is necessary. Use assistants as needed to offer adequate visualization. Richardson or Pratt retractors may be placed inside of the vagina to maximize the view.

McROBERTS MANEUVER

Apply the McRoberts maneuver if the fetal head does not deliver. The McRoberts maneuver is easy to perform (Figure 164-7). Place an assistant on each side of the patient. Hyperflex the mother's thighs onto her abdomen (Figure 164-7A). Instruct the assistants

FIGURE 165-5. Delivery of the arms. **A.** Insert the dominant hand along the humerus of the anterior arm. Apply traction (arrow) to flex the elbow. **B.** Deliver the arm. **C.** Gently rotate the fetus so that the other arm presents anteriorly.

FIGURE 165-6. Delivery of the fetal head.

FIGURE 165-7. The Mauriceau-Smellie-Viet maneuver.

to maintain support of the hyperflexion while applying suprapubic pressure (**Figure 164-7B**). This results in flattening of the lumbosacral curve with rotation of the pubic symphysis cephalad (**Figure 164-7C**). Perform the manual extraction.

MAURICEAU-SMELLIE-VIET MANEUVER

Perform the Mauriceau-Smellie-Viet maneuver if the McRoberts maneuver is unsuccessful in the spontaneous delivery of the head (**Figure 165-7**). Rest the body of the infant on the dominant arm. Place the index and middle finger of the dominant hand on the fetal maxilla. Apply pressure to the maxilla to maintain the fetal head in flexion. **Do not place the fingers on the fetal mandible or in the fetal mouth.** Place the nondominant hand on the posterior aspect of the fetal neck and shoulders. Slightly elevate the fetal body from the horizontal plane.

Exert continued and gentle downward traction with both hands until the occiput moves under the mother's pubic symphysis. **Never hyperextend the fetal trunk to avoid spinal cord injuries. Never apply pressure to the mandible or the fetal mouth during this maneuver. The force applied to the mandible or mouth can dislocate the mandible.** Instruct an assistant to apply firm and gentle suprapubic pressure in conjunction with gentle downward traction by the Emergency Physician. Continue this process until the head delivers.

FORCEPS-ASSISTED DELIVERY OF THE HEAD

The utilization of forceps may be warranted if none of these maneuvers is successful.^{16,18} The Piper forceps have a minimal pelvic curve and allow direct application to the fetal head. They are used solely for the delivery of the head in a breech delivery. **Forceps-assisted delivery can result in significant injury to the fetus and the mother. The use of the Piper forceps is not recommended unless the Emergency Physician has training and experience in their proper use.**

Apply the Piper forceps. Instruct an assistant to hold and elevate the fetal trunk slightly above the horizontal plane (**Figure 165-8A**). Kneel below the fetus. Insert the forceps directly into the vagina and along the fetal head. Apply the right forceps blade. Grasp the blade in the left hand. Place the right hand along the left fetal parietal bone between the fetal head and the right maternal pelvic side wall. Insert and apply the forceps blade. Instruct the assistant to hold the blade in this position. Apply the left forceps blade. Grasp the blade in the right hand. Place the left hand along the right fetal parietal bone between the fetal head and the left maternal pelvic side wall. Insert and apply the forceps blade. Gently join the forceps handles while avoiding excessive pressure.

Apply gentle downward and outward traction to the forceps blades to deliver the fetal head (**Figure 165-8B**). Slowly elevate the plane of the fetal trunk toward the maternal abdomen as the fetal face delivers. **Do not hyperextend the fetal neck.** Stop the extraction as the mouth appears. Gently suction the fetal mouth. Deliver the head.

DÜHRSSSEN'S INCISIONS

Perform Dührssen's incisions if the fetal head is entrapped, if other methods of extraction have failed, or if you are unfamiliar with the use of forceps (**Figure 165-9**). Dührssen's incisions consist of two to four incisions placed circumferentially around the cervix. **The two required incisions are at the 10 and 2 o'clock positions.** Additional incisions can be made at the 5, 6, and/or 7 o'clock positions. **The cervix must be more than 70% effaced and dilated more than 6 cm for the procedure to be successful and to prevent significant hemorrhage.**

FIGURE 165-8. Forceps-assisted delivery of the head. **A.** Application of the forceps. **B.** Delivery of the fetal head.

FIGURE 165-9. Dührssen's incisions. **A.** The incisions. **B.** Repair of the incisions.

Grasp two pairs of ring forceps. Grasp the cervix around the point of the incision. For example, place ring forceps at the 9 and 11 o'clock positions to make the 10 o'clock incision (**Figure 165-9A**). Make the incisions 2 to 3 cm in length with straight Mayo scissors. Deliver the fetal head.

PERSISTENT FETAL HEAD ENTRAPMENT

The fetal head may fail to deliver despite the maneuvers described above. True cephalopelvic disproportion must be differentiated from cervical entrapment (i.e., inadequate cervical dilation). The options are limited in the rare case of a true cephalopelvic disproportion. The Emergency Physician can perform a symphysiotomy (Chapter 168), the fetal body can be pushed back into the uterus and a cesarean section performed, or an experienced Obstetrician may perform a destructive procedure if the fetus is nonviable.

TOTAL BREECH EXTRACTION

Breech extraction is to be performed only in the rare instances of a second twin presenting in a breech position, extreme fetal distress without the capability of performing a cesarean section, and/or umbilical cord prolapse that does not allow time for setup or performance of a cesarean section.^{3,18-20}

Use ultrasound if available to identify the fetal legs and feet. This will ensure grasping of the appropriate extremity. Reach into the lower uterine segment with the dominant hand and firmly grasp the fetal feet. Place the fingers around the fetus's ankles with the index finger between the two ankles (**Figure 165-10A**). Apply continuous and firm traction in a downward and outward direction. Deliver the fetal feet and legs through the vaginal opening (**Figure 165-10A**). Continue to apply traction to deliver the fetus to the level of the buttocks (**Figure 165-10B**). Instruct an assistant to support the fetus. Perform a midline episiotomy if necessary. Deliver the fetus to the level of the umbilicus. Grasp the bony sacrum and pelvis. The remainder of the technique is as described previously.

COMPLETE AND INCOMPLETE BREECH DELIVERIES

Complete and incomplete breech deliveries may occur in the same fashion as the frank vaginal breech delivery. The one exception is that one or both feet may already be extended and not require attention.³ There is an increased risk of head entrapment, umbilical cord entanglement, and umbilical cord prolapse.^{3,10,13} This is the basis of the recommendation for cesarean delivery in these cases.^{3,10,13} One randomized trial reported non-frank vaginal breech delivery to be relatively safe.^{3,13}

FIGURE 165-10. Breech extraction. Reach into the uterus and grasp the fetal ankles. **A.** Apply traction to deliver the feet and ankles. **B.** Delivery of the buttocks.

ASSESSMENT

The two patients must now be assessed and treated.²¹ A second Physician or neonatal team can evaluate and resuscitate the infant if available.²¹ Determine the infant's Apgar score. Examine the infant for birth trauma and signs of prematurity (e.g., fusing of eyelids), as both correlate with perinatal morbidity and mortality.

Perform the maternal assessment simultaneously with that of the neonate. Offering reassurance to the mother while delivering the placenta (Chapter 162) and evaluating for postpartum hemorrhage (Chapter 166) is of the utmost importance.

AFTERCARE

The Apgar scores for infants delivered from a breech position are generally slightly lower than from a vertex delivery. The infant may show some initial signs of short-term and generally clinically insignificant hypoxia.

Postpartum recovery for the mother is generally uneventful. Observe her for evidence of infection or symptomatic anemia. Monitor urinary output for the presence of urinary retention if regional anesthesia is used or if there is significant perineal trauma.

Deliver the placenta and repair the cervix if there are any lacerations or Dührssen's incisions. An episiotomy, perineal laceration, and/or vaginal laceration must be repaired (Chapter 163). Initiate uterine massage. Administer Pitocin intramuscularly following delivery of the placenta.

It is vital that postpartum hemorrhage be managed to prevent maternal morbidity and mortality. Grasp the base of each cervical incision or laceration to decrease the bleeding. Do not waste time attempting to locate it if the distal angle is difficult to visualize. Apply traction to the proximal edges of the incision or laceration with ring forceps. Alternatively, place 2–0 chromic, Dexon, or Vicryl sutures along the edges of the cervical incision or laceration that can be visualized. Place progressively proximal interrupted sutures until the base is completely visualized (**Figure 165-9B**). Apply traction to the sutures to better visualize the cervical incision or laceration.

COMPLICATIONS

Maternal complications associated with the performance of a vaginal breech delivery include episiotomy extension, hematomas (i.e., vaginal or pelvic), infection, lacerations (i.e., cervical, perineal, and/or vaginal), and postpartum hemorrhage.

Neonatal complications include anoxia (i.e., perinatal asphyxia), arrest of head decent, brachial nerve palsy, cephalohematomas, cerebral hemorrhage, cerebral palsy, death, fractures (e.g., clavicular, cranial, and femoral), hypoxia, lacerations, spinal cord injuries from head hyperextension, and umbilical cord prolapse.^{1,3,10,11,13,22-27} Studies suggest that the occurrence of these complications may be greatly influenced by the urgency of the delivery rather than solely the method of delivery.³ An adequately prepared Emergency Physician may not be able to prevent these complications but will less likely contribute to them.

There are complications that are unique to the breech presentation. Head entrapment is a potentially serious complication of breech delivery. The head is often the largest part of the fetus. There is no time for molding of the breech head. Umbilical cord compressions can contribute to fetal acidosis, hypoxia, and death if the fetal head does not deliver easily after delivery of the torso. Attempts to expedite delivery can result in maternal and fetal trauma. The risk of head entrapment is especially high in the preterm infant before 30 weeks as the head is large in relation to the body.²⁸

Non-frank breech presentation has an increased incidence of umbilical cord prolapse as the presenting part may not completely

occlude the cervix. The risks of umbilical cord prolapse and prematurity associated with the breech presentation are listed in **Table 165-1**.

SUMMARY

Perinatal morbidity and mortality are improved with a planned cesarean section when compared to a planned vaginal delivery for the delivery of a breech infant. A cesarean delivery may not be an option in the emergency setting. Increased morbidity and mortality may be seen with estimated fetal weights of less than 1500 gm or greater than 4000 gm, single or double footling presentation, a diminished maternal pelvis, cephalic hyperextension, or in the hands of an inexperienced Emergency Physician. Cesarean section is preferable in these instances if available. The Emergency Physician managing an imminent breech delivery should be well aware of the potential complications, the relative indications for cesarean delivery, and the techniques and tools for vaginal delivery to lessen the inherent risks to the infant and mother.

Postpartum Hemorrhage Management

Leah W. Antoniewicz

INTRODUCTION

Postpartum hemorrhage, or excessive blood loss following delivery, is the leading cause of maternal death worldwide. It is traditionally defined as blood loss greater than 500 mL after vaginal delivery and 1000 mL after a cesarean section.^{1,2} This is impractical because the normal blood loss is believed to be 300 to 600 mL following a vaginal delivery and 900 to 1200 mL following a cesarean section.^{3,4} Postpartum hemorrhage has also been defined as blood loss that results in a decrease in the hematocrit of greater than 10 points between admission and the postpartum period which corresponds to the 97th percentile of vaginal and 92nd percentile of cesarean deliveries.^{1,3} A clinically useful definition is excessive bleeding that results in signs and/or symptoms of hypovolemia (e.g., dizziness, hypotension, oliguria, palpitations, syncope, shortness of breath, and tachycardia), which corresponds to a 10% or more loss in total blood volume.⁴ Postpartum hemorrhage can occur at sites within or external to the genitourinary tract (**Table 166-1**).

The incidence of postpartum hemorrhage ranges from 2% to 3% of pregnancies in the United States.⁵ The risk factors for postpartum

hemorrhage are listed in **Table 166-2**. The etiologies are varied (**Table 166-3** and **Figure 166-1**). Primary postpartum hemorrhage accounts for greater than 90% of all cases and occurs within 24 hours of delivery. Uterine atony (i.e., lack of uterine contraction) is by far the most common cause. This is often the result of excessive bleeding from the placental implantation site. Trauma (e.g., genital tract lacerations, surgical incisions, or uterine rupture) is the second most common etiology. Hemorrhage can be associated with a considerable drop in hematocrit before clinical symptoms occur and result in significant maternal complications.

Secondary postpartum hemorrhage occurs more than 24 hours after delivery and up to 12 weeks postpartum. It is usually the result of excessive bleeding from the placental implantation site or retained products of conception but can also be caused by an infection or coagulation defects.^{6,7} This chapter reviews the pathophysiology of early postpartum hemorrhage, discusses the diagnosis and assessment of postpartum hemorrhage, and concludes with strategies for treatment.

ANATOMY AND PATHOPHYSIOLOGY

The most common causes of postpartum hemorrhage are uterine atony (70% to 90%), genital tract trauma (5% to 8%), retained products of conception (3% to 5%), and hematologic or coagulopathic abnormalities (< 2%). Uterine inversion is a rare cause of postpartum hemorrhage. Risk factors for uterine atony include anesthesia, augmented or induced labor, chorioamnionitis, high parity, overdistention of the uterus, previous postpartum hemorrhage, prolonged third stage of labor, and use of uterine relaxing agents.¹ Genital tract

TABLE 166-3 Etiologic Associations for Postpartum Hemorrhage

Altered maternal anatomy	Pitocin use, prolonged
Altered uterine contractility	Placental abruption
Asian ethnicity	Placenta previa
Cesarean section dehiscence or rupture	Postpartum hemorrhage history
Chorioamnionitis	Precipitous delivery
Coagulopathy	Preeclampsia
Compound delivery	Prolonged or tumultuous labor
Disseminated intravascular coagulation	Reproductive tract anomalies
Dührssen's incisions	Retained placental fragments
Endometritis	Shoulder dystocia
Episiotomy	Tissue lacerations
Fetal scalp electrode injury	Tocolytic use
General anesthesia	Trauma
Grand multiparity	Uterine anomalies
Hispanic ethnicity	Uterine atony
Infection	Uterine inversion
Intrauterine pressure catheter injury	Uterine leiomyomata
Myomectomy dehiscence or rupture	Uterine pressure monitor injury
Occiput posterior delivery	Uterine rupture
Operative delivery	von Willebrand's coagulopathy

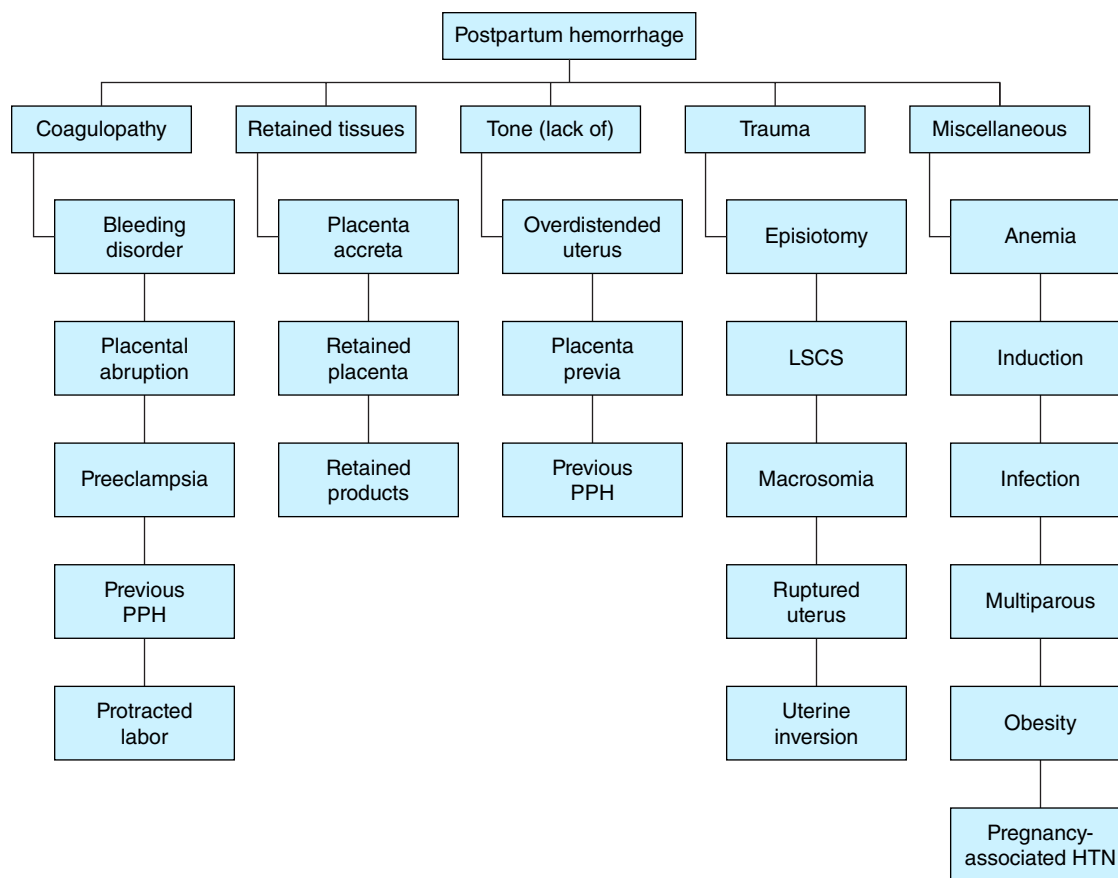

FIGURE 166-1. Some of the more common etiologies of postpartum hemorrhage. HTN, hypertension; LSCS, lower segment cesarean section; PPH, postpartum hemorrhage.

injuries include episiotomies, hematomas (e.g., broad ligament, ischiorectal fossa, vaginal, and vulvar), lacerations (e.g., uterine or vaginal), and uterine rupture. Retention of all or part of the placenta interferes with uterine contraction and results in continued bleeding from the placental implantation site. Hematologic abnormalities include disseminated intravascular coagulation, von Willebrand's disease, and other less common disorders (i.e., acquired, congenital, or inherited).

The plasma volume increases in a normal pregnancy by approximately 40% and the red cell mass by 25%, resulting in a hypervolemia of approximately 1500 to 2000 mL.^{6,8} This compensates for typical blood losses. **Visual estimates of blood loss are inaccurate, especially if blood is mixed with amniotic fluid. Weigh all pads for an accurate assessment and use 1 gm = 1 mL of blood.** The signs and symptoms of postpartum hemorrhage include diaphoresis, dizziness, fatigue, hypotension, measurable blood loss greater than 500 mL, oliguria, pallor, palpitations, shortness of breath, syncope, and tachycardia. Suspect a concealed hemorrhage from a broad ligament hematoma, uterine rupture, or vaginal hematoma if the patient is symptomatic in the absence of external blood loss.

Patients at risk for postpartum hemorrhage require blood typed and crossmatched on admission. Obtain a blood chemistry, coagulation studies (e.g., fibrinogen, international normalized ratio, prothrombin time, partial thromboplastin time, and thromboelastography). Most women who hemorrhage, however, have no risk factors. Leading risk factors associated with early postpartum hemorrhage in vaginal birth include arrest of descent, chorioamnionitis, mediolateral episiotomy, multiple gestations, preeclampsia, previous postpartum hemorrhage, prolonged third stage of labor, and soft tissue lacerations.^{1,3} Other risk factors are listed in **Tables 166-2 and 166-3**. Surgical deliveries are often associated

with increased blood loss when compared with vaginal deliveries. Inhalation anesthesia, especially with halogenated agents, increases the risk for postpartum hemorrhage and should be used sparingly in high-risk cases.^{8,9}

INDICATIONS

All postpartum hemorrhage must be controlled as soon as possible to prevent maternal morbidity and mortality (Figure 166-2).² Injuries and lacerations are most common with difficult deliveries (e.g., operative vaginal deliveries and use of an episiotomy). Carefully examine the cervix and vagina for injury immediately following delivery of the infant and placenta. Note these injuries and anticipate the possibility of postpartum hemorrhage.

CONTRAINDICATIONS

There are no absolute contraindications to the management of postpartum hemorrhage. Medication therapies for postpartum hemorrhage for atony may have significant side effects. Avoid undiluted rapid intravenous (IV) infusions of oxytocin which can cause hypotension. Ergots (e.g., methylergonovine) are potent vasoconstrictors and should be administered intramuscularly. They are contraindicated in the presence of cardiac disorders, coronary artery disease, hypertensive disorders, preeclampsia, Raynaud's phenomenon, and scleroderma. Prostaglandin F (PGF) is contraindicated in patients with active asthma as it can incite severe bronchospasm in sensitive individuals.⁷ PGF may result in vasoconstriction of the pulmonary bed.⁷ The side effects include diarrhea, fever, and tachycardia. Avoid prostaglandin E₂ (PGE₂; i.e., Prostin) in hypotensive patients. Human recombinant factor VIIa (NovoSeven) is an expensive

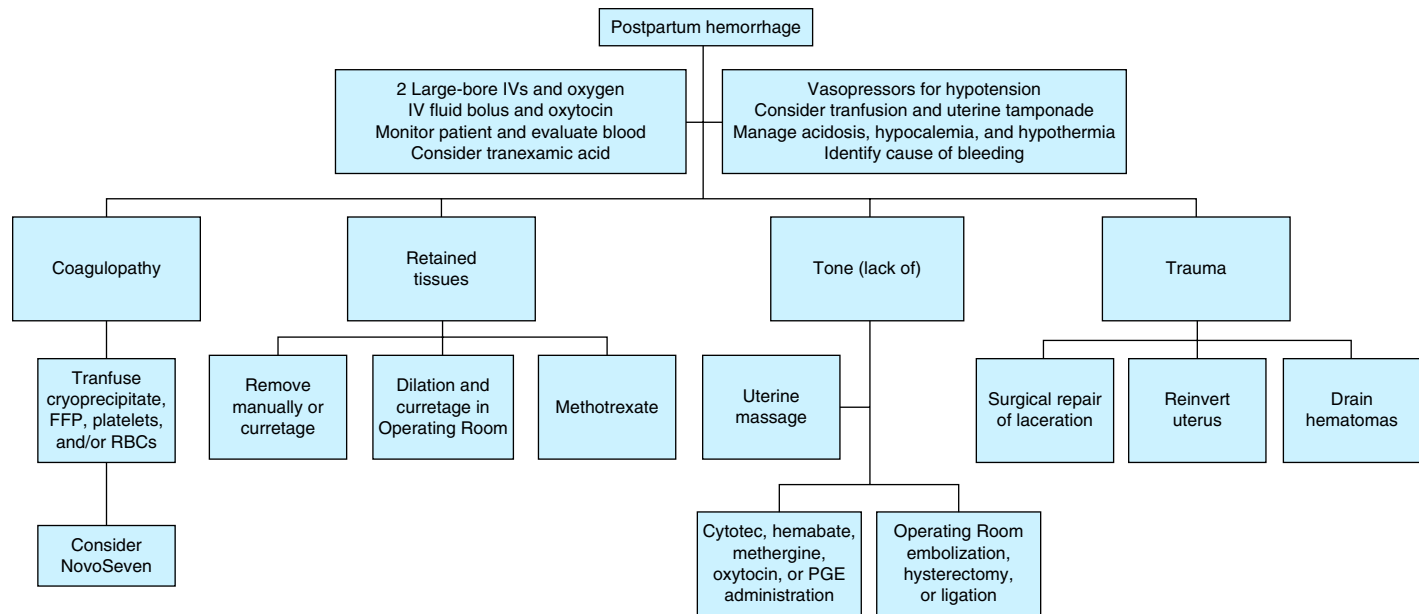

FIGURE 166-2. Treatment of postpartum hemorrhage. FFP, fresh frozen plasma; RBCs, red blood cells.

treatment for life-threatening hemorrhage and can cause subsequent thromboembolism. Ensure the balloons used do not contain latex if allergic and only contain silicone.

Indications for sending the patient directly to the Operating Room are uncommon. **Significant arterial bleeding requires surgery or embolization and not temporizing measures.** Congenital anomalies of the uterus, uterine distortion (e.g., leiomyomas), and uterine rupture (i.e., actual or suspected) require surgical treatment. Purulent infections of the genital tract might be spread by uterine manipulation.

EQUIPMENT

- Sterile gown and gloves
- Face mask with eye shield or goggles
- Surgical hat
- Chlorhexidine or povidone iodine solution
- Foley catheter
- Gauze sponges
- Sponge-tipped applicators, large
- Sterile delivery drapes
- Alcohol swabs
- 16 to 18 gauge needle for IV access
- 10 mL syringe
- 22 to 25 gauge needle for injection of local anesthetic
- Weighted vaginal speculum or Sims retractor
- 2 right angle (Heaney) retractors
- 4 ring forceps
- Straight Mayo scissors or sterile scalpel
- 2–0 or 3–0 suture: monofilament polydioxanone (Monocryl) or polyglactin (Vicryl)
- PPH Butterfly (Figure 166-3)
- Bakri Postpartum Balloon, optional (Figure 166-4)
- ebb Complete Tamponade System, optional (Figure 166-5)
- BT-Cath (Figure 166-6)

- Sengstaken-Blakemore tube, optional (Chapter 81)
- 3 Foley catheters if balloon is not available, optional (Chapter 173)
- Poiesis Duette Dual-Balloon (Figure 166-7)
- Packing forceps

MEDICATIONS

- Local anesthetic solution (e.g., bupivacaine, lidocaine, or mepivacaine)
- Oxytocin (i.e., Pitocin)
- 15-methyl PGF_{2α} (i.e., Hemabate, Carboprost)
- Methylergonovine maleate (i.e., Methergine)
- Misoprostol or PGE₁ (i.e., Cytotec)
- Dinoprostone or PGE₂ (i.e., Prostin)
- 5000 U of thrombin in 5 mL of sterile saline
- Factor VIIa (i.e., NovoSeven)

PATIENT PREPARATION

Obtain an informed consent if possible and time allows. Explain the risks, benefits, and alternative procedures to the patient and/or their representative. Include the possibility of the Operating Room and a hysterectomy. Obtain a signed informed consent for the procedure and place this in the medical record. Verbal consent can be documented in the medical record if the patient cannot sign for some reason.

The initial management is aimed at stabilizing the mother and identifying the bleeding source.² Apply bimanual compression (Figure 166-8) which will control most hemorrhage and obtain help. Establish IV access at two sites with 16 to 18 gauge angio-catheters. Type and crossmatch the patient for any required blood components. Obtain a complete blood count, chemistry, and coagulation profile.¹⁰ Place a Foley catheter to monitor urine output and to allow the uterus to contract. Regulate and monitor fluid intake carefully to avoid acute respiratory distress syndrome or dilutional disseminated intravascular coagulation (DIC).

Identification of the origin or site of bleeding is critical.² Uterine hypotonia or atony is the most frequent source of hemorrhage. Uterotonics (e.g., oxytocin) are usually administered concurrently with a

FIGURE 166-3. The PPH Butterfly. **A.** The device is folded flat for insertion. **B.** The handles are brought together to create the triangular platform. **C.** Holding the device longitudinally. **D.** The device can be held from above if the patient is on a bed. (Used with permission from reference 23.)

complete examination of the uterus. Palpation will often exhibit a soft and spongy (i.e., boggy) uterus that may be increasing in size due to the accumulation of clots and blood within the endometrial cavity. Clear these to allow for adequate uterine contractions. Continued bleeding from the endometrial cavity through the cervical os is always present. **A well-contracted uterus does not bleed significantly in the absence of a severe coagulopathy.** Examination of the uterus is performed by palpation of the fundus with the nondominant

hand and manual exploration of the uterine cavity with the other. Use ultrasound to identify the presence of any clots or placental tissue that may require manual removal and/or curettage.¹¹

Continued hemorrhage with a firm uterus indicates bleeding from another source (e.g., cervix, lower uterine segment, the cervix, or the vagina). **Examine all areas carefully, even after hemorrhage is noted at one site, as there may be more than one source of hemorrhage.** Begin at the most distal aspects of the genital tract and work proximally.

TECHNIQUES

TRANEXAMIC ACID

Tranexamic acid (TXA) is a synthetic derivative of lysine. It is an antifibrinolytic that prevents the conversion of plasminogen to plasmin and inhibits the degradation of fibrin clots by plasmin. TXA can be used prophylactically to prevent postpartum hemorrhage.¹²⁻¹⁴ The studies so far have limited information on its prophylactic use. Prophylactic use reduces blood loss, postpartum hemorrhage, and the need for transfusion.¹⁴ It can be used for postpartum hemorrhage management when bleeding is noted.¹⁵⁻¹⁹ The best evidence so far is from the WOMAN trial.¹⁹ TXA decreased deaths and had no adverse effects. Safety regarding long-term effects is not well studied.

UTERINE ATONY

Administer oxytocin and fundal (i.e., transabdominal) massage just after delivery of the placenta. These can usually result in a

FIGURE 166-4. The Bakri Balloon (Cook Medical, Bloomington, IN).

FIGURE 166-5. The ebb Complete Tamponade System (Clinical Innovations, Murray, UT).

contracted, firm and rock-like fundus. However, the uterus may never become firm or may relax again.

Begin transabdominal uterine massage for uterine atony to promote uterine muscle contractions. Use one or two hands to palpate the uterus through the abdominal wall and rhythmically press downward in a circular motion. Massage in a firm but gentle manner without pushing the uterus through the birth canal (i.e., inversion or prolapse). **Avoid overly vigorous massage which can injure the broad ligament vasculature.**⁸

Administer an oxytocin infusion at the same time as fundal massage. Inject 40 U of oxytocin into 1 L of sterile IV normal saline

FIGURE 166-6. The BT-Cath (Utah Medical Products Inc., Midvale, UT).

FIGURE 166-7. The Poiesis Duetto (Poiesis Medical LLC, Jupiter, FL).

Administer the oxytocin-saline solution over 10 minutes. Alternatively, administer 10 U of oxytocin intramuscularly. Repeat the oxytocin dose if atony persists.

Continued bleeding requires the initiation of bimanual uterine compression. Massage the posterior aspect of the uterus with the

FIGURE 166-8. Bimanual uterine compression.

abdominal hand and the anterior aspect of the uterus through the vagina with the other hand clenched into a fist (**Figure 166-8**).⁸ Use the intravaginal hand to massage the uterus against the external pressure applied by the abdominal hand. **This allows for more effective uterine massage.** Perform manual uterine exploration if the massage fails to control the hemorrhage. Manual uterine exploration can localize and extract any placental fragments remaining within the uterus.

Begin second-line medications to contract the uterus if bimanual massage is ineffective and consult an Obstetrician. Several options are available depending on what medication is readily available.²⁰ Administer 250 µg of Hemabate (i.e., PGF₂) intramuscularly or transabdominally into the uterine musculature every 15 to 90 minutes to a maximum total dose of 2 mg. Only use Hemabate in non-asthmatic patients. It is a potent stimulator of uterine contraction.²¹ Administer 0.2 mg of methylergonovine (i.e., Methergine) intramuscularly in the nonhypertensive patient. This is an ergot derivative that causes uterine contraction. The dose may be repeated every 2 to 4 hours. Misoprostol (i.e., Cytotec) is quickly absorbed, inexpensive, and safe to use in patients with hypertension or asthma. Administer 400 µg in tablets buccally for faster peak absorption or rectally. This dose may be repeated every 4 to 6 hours. Monitor the patient's temperature as pyrexia can occur. Administer dinoprostone (e.g., Prostin) 20 mg rectal suppository as continued vaginal bleeding may expel the suppository. This may be repeated every 2 hours. Consider using 16.7 to 200 µg/kg IV of factor VIIa concentrate (i.e., NovoSeven). This agent has the potential to cause intravascular clot formation with subsequent end organ damage.²²

Sustained bleeding requires an Obstetrician for curettage or other operative management. A discussion of these techniques is beyond the scope of this chapter. Tamponade the uterus while waiting for the Obstetrician as described below. Consult an Interventional Radiologist and consider uterine artery embolization.

The PPH Butterfly was developed to stop postpartum hemorrhage (**Figure 166-3**).²³ The Butterfly achieves the benefits of bimanual compression but is less invasive (i.e., a hand is not inserted into the patient). The size and shape of the compression platform are based on a pessary. It is slim, easy to insert, and acceptable to women. The Butterfly is held in place by the physician with a handle on it. It can also be held in place by an assistant or wedged on the bed. This device is not yet available commercially.

BALLOON TAMPONADE

A balloon within the uterus can tamponade the hemorrhage.^{24,25} Balloons are safe and effective. They are incorporated into postpartum hemorrhage pathways.²⁵ Their use may decrease morbidity and mortality. Balloons are easy to insert and use. The side effects are minimal. This is only a temporizing measure to control hemorrhage.

The Bakri Balloon is a dual-channel and single-use device that was designed to tamponade the uterus for postpartum bleeding (**Figure 166-4**).²⁶⁻²⁹ Advantages include conformation to the shape of the endometrial cavity, low risk of uterine perforation, ready availability to use, and ease of use. The Bakri Balloon is made of silicone and contains no latex. Ensure that no placental fragments remain in the uterus (e.g., palpation or ultrasound).

Clean the cervix and vagina with antiseptic solution (e.g., povidone iodine). Gently grasp the balloon with ringed forceps. Insert it into the uterus transcervically, under ultrasound guidance if possible or by palpation, to the fundus. **Ensure that the entire balloon is within the uterus.** Hold the tubing in place at the cervical os to ensure the balloon remains above the cervix. Instill 300 to 500 mL of sterile saline to inflate the balloon. **Use only sterile fluid and not air or another gas. Using a gas can result in an air embolism if the balloon is perforated.** Clamp the tubing. Palpate the cervix or use ultrasound to ensure uterine placement. Apply gentle traction to maximize lower

FIGURE 166-9. Vaginal packing with a balloon in the uterus.

uterine segment tamponade. Secure the tube to the patient's thigh or attach a 500 mL saline bag to the tubing as a weight. Blood will drain from sites proximal to the tube. Consider packing the vagina to prevent the balloon from migrating downward into the vagina (**Figure 166-9**). Tamponade has failed if the bleeding is excessive and continues. Bleeding is occurring above the balloon if the fundal height increases. Flush the drainage tube with 10 mL of sterile saline. The Bakri Balloon can remain in place for up to 24 hours.

The ebb Complete Tamponade System (Clinical Innovations, Murray, UT) can also be used up to 24 hours (**Figure 166-5**). It is a dual-balloon that conforms to the endometrial cavity.³⁰ The 750 mL intrauterine balloon is larger than most others. The uterine balloon has three lumens to enable balloon inflation/deflation, uterine irrigation, and uterine drainage. The dual-balloon anchors the device and eliminates the vaginal packing with the inflated vaginal balloon. The vaginal balloon has one lumen to inflate and deflate the balloon. The ebb is made of polyurethane and contains no latex.

The ebb catheter is used similar to the Bakri Balloon. Collapse the uterine balloon loosely. Insert the device through the cervical os and to the uterine fundus. Attach the fluid bag to the infusion port spike. Inflate the uterine balloon by squeezing the fluid bag. This transfers the fluid from the bag to the intrauterine balloon. Transfer approximately 250 mL to the balloon. Continue to fill the balloon gradually until the desired fluid volume is reached and tamponade is achieved. **Rapid infusion can rupture the uterus.** Unlock the vaginal balloon and slide it to the desired location. Lock the vaginal balloon in place. Fill the vaginal balloon up to 300 mL maximum. Apply traction if desired and secure the catheter as above.

The BT-Cath (Utah Medical products LLC, Midvale, UT) is a silicone catheter that contours to the shape of the endometrial cavity (**Figure 166-6**). It is made of silicone. The soft balloon is easy to insert. The dual-lumen catheter allows infusion of fluid to fill the balloon and monitor uterine drainage. The set includes the catheter, stopcock, syringes, and valves. Assemble the system (**Figure 166-6**). Insert the catheter into the uterus. Spike the IV bag and draw fluid into the syringe. Pump fluid into the balloon.

Use a Sengstaken-Blakemore tube if a tamponade balloon is not available (Chapter 81). These are often available in the Emergency Department. Insert the Sengstaken-Blakemore tube into the uterine cavity. Inflate the gastric balloon with 250 mL of sterile saline. Check placement and apply slight traction. Secure the tube as described above. Flush the lumen of the Sengstaken-Blakemore tube with 10 mL of sterile saline to clear any clots or blood collected behind the balloon.

FIGURE 166-10. The uterus and vagina are packed with Kerlix gauze.

Use Foley catheters (Chapter 173) with a 30 mL bulb if a Bakri Balloon or a Sengstaken-Blakemore tube is not available. Gently grasp the end of the Foley catheter with ring forceps just below the bulb. Insert it completely into the uterus. Securely hold the catheter in place. Instruct an assistant to instill 60 mL of sterile saline into the bulb. Repeat this procedure with up to two more Foley catheters to completely fill the endometrial cavity and tamponade the hemorrhage.

The Duette (Poiesis Medical LLC, Jupiter, FL) was developed as an alternative to the Foley (**Figure 166-7**). The dual-balloon catheter was meant for bladder catheterization. Drainage holes are located between the two balloons. It has been placed in the endometrial cavity for tamponade of postpartum hemorrhage.

UTERINE PACKING

Consider packing the uterus if none of the previously mentioned devices are available or if they fail (**Figure 166-10**).³¹ Packing is effective, quick, and safe. Tightly pack the uterus starting at the fundus and working outward. Use a 4 inch wide gauze roll (e.g., Kerlix) soaked in 5 mL sterile saline and 5000 U of thrombin. Administer IV broad-spectrum antibiotics if the uterus is packed with gauze. Carefully monitor hematocrit, urine output, and uterine size. Blood may collect in the fundus with all forms of tamponade.

RETAINED PLACENTA

Postpartum hemorrhage, whether primary or secondary, may be caused by retained placental tissue within the uterine cavity. The retained placental tissue may be completely attached, partially separated, or completely separated from the uterine wall. Placental fragments completely attached to the uterine wall may not be removable manually and may require a curettage or laparotomy. Completely or partially separated placental fragments may remain due to a closed cervix entrapping them or inadequate uterine contractions. Manual extraction will remove the retained placental fragments. **Administer adequate anesthesia. Administer a uterine relaxant to relax the lower uterine segment in the absence of uterine atony. This must be performed aseptically.**

Insert a sterile gloved hand through the open cervix and into the uterine cavity (**Figure 166-11**). Place the other hand on the abdominal wall and over the fundus of the uterus. Gently and carefully sweep the fingers around the circumference of the uterus to determine if any fragments of placenta remain. Identify the edge of the fragment if it has not separated from the uterine wall. Gently place the fingertips under the edge of the fragment. Gently remove any placental fragments from the uterus by alternating abducting, adducting, and advancing the fingers in a scissors-like motion until

FIGURE 166-11. Manual removal of the placenta. The fingers are abducted, adducted, and advanced continually (in a scissor-like motion) in this sequence of movements until the placenta is completely detached.

the entire fragment is separated from the uterus wall. Grasp and gently remove the placental fragments when separated from the uterine wall. **Ensure that the entire placenta is removed. Reinsert a hand into the uterine cavity and palpate for any remaining placental fragments. Examine the placenta carefully to make sure that no cotyledons are missing.**

Determine if any placental membranes are retained. Reinsert the gloved hand covered with a gauze sponge (**Figure 166-12**). Wipe the uterine walls with the sponge to collect any retained membranes. Remove the gauze sponge with any adherent membranes. Initiate IV oxytocin following removal of the placenta.

The placenta is likely embedded into the wall of the uterus if it does not manually separate. This is known as placenta accreta, percreta, or increta depending on the degree of myometrial penetration. Consult an Obstetrician as a laparotomy, hysterotomy, and possibly a hysterectomy will be required.

GENITAL TRACT INJURIES

Bleeding from the lower uterine segment, cervix, or upper vagina is difficult to diagnose and manage. The anatomic locations are awkward and difficult to visualize. Excessive bleeding makes visualization even more problematic. It may be almost impossible to see a small laceration or an individual bleeding vessel. **Do not attempt to repair a laceration that cannot be completely visualized as this could result in damage to other structures.** The uterotonic medications (e.g., oxytocin and the prostaglandins) are less effective due to the relative paucity of contractile muscle in these tissues. Consider packing the uterus with gauze or a vaginal pack if available. Management of excessive bleeding from this area may require a laparotomy with uterine artery embolization or a hysterectomy. Discussion of these techniques is beyond the scope of this chapter.

FIGURE 166-12. Manual removal of retained placental membranes.

LACERATION REPAIR

All bleeding lacerations must be repaired. Always make sure there is adequate exposure and visualization of the laceration. Insert a Foley catheter if the laceration is in proximity to the urethra. This ensures urethral patency and helps preclude urethral inclusion when placing sutures. Scrub the perineum with chlorhexidine or povidone iodine solution. Apply sterile drapes beneath the patient's buttocks, on the legs, and on the abdomen to prevent contamination from nonsterile areas. Provide anesthesia with the injection of local anesthetic solution directly into the laceration or with a nerve block (Chapter 163).

Thorough knowledge of the anatomy and awareness of where sutures are being placed are necessary to avoid perforation of any proximate viscera. Always use absorbable suture. Refer to Chapter 163 for complete details regarding the repair of an episiotomy. A brief description of the repair procedure is provided below.

FIRST-DEGREE LACERATIONS

First-degree lacerations involve the fourchette, the perineal skin, and/or the vaginal mucous membrane. They spare the underlying fascia and muscle. If the lacerations are small and hemostatic, they do not need to be repaired. Use continuous running 2-0 or 3-0 monofilament polydioxanone (i.e., Monocryl) or polyglactin (i.e., Vicryl) suture to close the vaginal mucosa and submucosa. Chromic gut suture is an alternative but causes more postprocedural pain until it is absorbed. Interrupted stitches may better approximate the laceration if it is very irregular. Approximate the cut margins of the hymenal ring with a stitch. Repair skin lacerations with subcuticular 3-0 stitches as they cause less perineal pain.⁸ An alternative is to place interrupted 3-0 stitches.⁸

SECOND-DEGREE LACERATIONS

Second-degree lacerations involve the perineal skin, vaginal mucous membrane, subcutaneous tissue, fascia, and muscles of the perineum but not the anal sphincter muscle. Repair is essentially the same as for an episiotomy but complicated by the irregularity of the laceration. Begin as in a first-degree laceration by repairing the vaginal mucosa and submucosa. Do not place the stitches too deep above the vaginal fornices to avoid injuring the ureters. Approximate the hymenal ring. Place interrupted 2-0 or 3-0 stitches to close the fascia and muscles of the lacerated perineum. Carry a continuous running stitch downward to unite the superficial fascia and then upward to close the subcutaneous tissue. Close the skin with a running subcuticular stitch, which is preferred, or interrupted stitches.

THIRD-DEGREE LACERATIONS

Third-degree lacerations involve a second-degree laceration that extends into the anal sphincter but not the rectal mucosa. Isolate, approximate, and stitch together the cut ends of the anal sphincter muscle with interrupted 2-0 Vicryl suture at the anterior, inferior, posterior, and superior portions of the muscle. The remainder of the repair is the same as that for second-degree lacerations.⁸

FOURTH-DEGREE LACERATIONS

Fourth-degree lacerations extend through the rectal mucosa to expose the rectal lumen. Approximate the torn rectal mucosa with running or interrupted 3-0 or 4-0 chromic gut sutures placed approximately 0.5 cm apart. Isolate and approximate the internal anal sphincter with 3-0 or 4-0 Vicryl or Monocryl suture. Proceed as with the repair of third-degree lacerations.⁸

CERVICAL LACERATIONS

Gently grasp each side of the cervical laceration with ringed forceps. Start at the apex of the laceration using 2-0 suture and close the laceration in a running pattern. **Do not stitch closed the endocervical canal.** Start at the highest point that can be visualized if the apex cannot be visualized and place the first stitch as a single interrupted stitch. Use the suture to apply gentle traction to identify the upper part of the laceration. Place interrupted 2-0 stitches to close the apex. Use a running stitch to close the lower part of the laceration.

ASSESSMENT

Thoroughly examine the patient to ensure the cessation of bleeding. **Any additional bleeding sites must be found and repaired.** Carefully monitor the patient's vital signs and urinary output. Manage any hypotension with fluid boluses and blood products. Follow serial complete blood counts if the patient has lost a significant amount of blood. A hematocrit less than 21% or persistent hypotension and tachycardia may require a transfusion. Manage hemodynamically stable patients expectantly. Continue to monitor blood parameters every 30 minutes and use these to guide treatment.¹⁰ Consult an Obstetrician for all patients with postpartum hemorrhage for repair in the Emergency Department or the Operating Room and patient admission.^{32,33} Consider consulting an Invasive Radiologist, after consulting the Obstetrician, for embolization and to avoid surgery.³⁴

Do not deflate the balloon catheter in the Emergency Department. This is best done by the Obstetrician after the tamponade of the hemorrhage. Deflate the balloon if it is no longer needed (i.e., the hemorrhage is stopped). Deflate the balloon slowly in increments in case bleeding resumes. Observe the patient between deflation increments until the balloon is empty. Cut the inflation lumen with a scissors for quick deflation.

AFTERCARE

The use of antibiotics has not been studied in comparison to not using them. Expert consensus is that administration of parenteral antibiotics decreases the rate of infection (i.e., cervicitis, endometritis, and vaginitis). All agree that antibiotics should be used if the vagina or uterus is packed.

The aftercare for postpartum hemorrhage is targeted toward the etiology of the bleeding episode. Warm sitz baths alternated with ice packs applied to the perineum three to four times a day will decrease inflammation and the risk of infection in patients with lacerations or episiotomies. Stool softeners will decrease the pain of defecation and the risk of wound dehiscence, especially with third-degree or fourth-degree lacerations. A high-fiber, low-residue diet may be helpful if the anal sphincter was involved. Prescribe oral analgesics for pain relief. Nonsteroidal anti-inflammatory drugs or acetaminophen provides adequate analgesia for most patients. Narcotic analgesics (e.g., acetaminophen with codeine, hydrocodone, or tramadol) may be necessary initially. Avoid formulations that increase constipation in patients with third-degree or fourth-degree lacerations.

Follow complete blood count values until the patient is asymptomatic and stable. Consider a transfusion if the patient's hematocrit is less than 25 or if the patient is symptomatic from anemia. Prescribe 325 mg of iron sulfate orally two to three times daily.

Follow-up therapy for uterine atony often includes the use of oxytocin (e.g., 20 to 40 U/L of IV fluid) for 12 to 24 hours. An alternative is oral Methergine or other uterotonic medications. There are no studies comparing the individual medications. Initiate therapy after consultation with an Obstetrician.

COMPLICATIONS

Maternal complications resulting from postpartum hemorrhage include acute renal failure, acute respiratory distress syndrome, coagulopathy (i.e., consumptive or dilutional), extreme fatigue, postpartum endometritis, Sheehan's syndrome, shock, the need for blood transfusion, and the need for surgical intervention (e.g., dilatation and curettage or laparotomy) and its associated complications. Complications associated with pharmacologic therapy can be avoided by carefully selecting the appropriate agent for each patient as noted previously.

Intrauterine balloons can migrate or slip into the vagina (Figure 166-13). This risks rupture of the cervix or vagina. Prevent

FIGURE 166-13. Improper uterine balloon placement or migration.

migration by using a dual-balloon system, frequently checking balloon location, not applying traction, or packing the vagina.

SUMMARY

Postpartum hemorrhage is a serious and potentially lethal condition. Early identification of risk factors and a prompt response to the early signs and symptoms of postpartum bleeding will decrease the morbidity and mortality. Always consult an Obstetrician immediately if the patient experiences postpartum hemorrhage.

Perimortem Cesarean Section (Perimortem Cesarean Delivery)

Jeanne A. Noble

INTRODUCTION

The term "perimortem cesarean delivery" (PMCD) was introduced in 1986 to describe a cesarean section performed during cardiopulmonary resuscitation (CPR) of the mother and initiated within the first 4 minutes following maternal arrest.¹ **The goals of this procedure are to improve the effectiveness of maternal resuscitation as well as to increase the chances of fetal survival.**^{2,3} For more than two decades, the PMCD has been included as part of the algorithm for management of cardiac arrest in pregnant patients.⁴⁻⁷

The incidence of cardiac arrest during pregnancy is estimated to be about 1 in 30,000 pregnancies.^{8,9} According to a review of reported PMCDs from 1985 to 2004, the most frequent causes are anesthesia, cardiogenic, eclampsia, emboli (e.g., amniotic fluid and air), intracranial hemorrhage, magnesium overdose, sepsis, spontaneous uterine rupture, and trauma.²

Trauma is the leading cause of death in women of reproductive age and accounts for 25% to 50% of maternal morbidity. Major maternal injury is associated with a fetal loss rate of 45% to 50%. **The primary goal in the management of the severely injured pregnant patient is maternal assessment and stabilization. Prompt attention to the needs of the gravid patient can save the life of both the fetus and the mother.** There are occasions when emergent cesarean delivery is the intervention most likely to save the life of the mother, the fetus, or both.

This procedure is best performed by a qualified Surgeon in the Operating Room. However, in the case of maternal arrest out of hospital or in the Emergency Department, valuable minutes should not be wasted transferring the patient to an Operating Room. Rather, the Emergency Physician should proceed with PMCD with the goal of fetal delivery by minute 5 after maternal arrest. It may also be performed for imminent maternal demise. PMCD is a key procedure that all Emergency Physicians need to be able to perform in the rare instance that it is required.

There are two basic conditions that must be met when considering PMCD. First, confirm that the uterine fundus reaches the mother's umbilicus (or higher) correlating with a gestational age of 20 weeks (or more). This is the point at which aortocaval compression by the uterus has a significant impact on maternal hemodynamics. Second, verify that the mother is pulseless and that noninvasive manual displacement of the uterus to her left side does not lead to return of spontaneous circulation (ROSC). **Proceed quickly to PMCD unless there is another obvious intervention that is likely to lead to maternal ROSC.**

ANATOMY AND PATHOPHYSIOLOGY

Important physiologic changes during pregnancy should be kept in mind in the event of maternal cardiac arrest.¹⁰ Cardiac output, blood volume, and heart rate all increase during pregnancy. Pulmonary and systemic vascular resistance decreases. Uteroplacental blood flow increases with the uterus receiving up to 30% of cardiac output. Aortocaval compression during the second half of pregnancy can result in decreased venous return to the heart, decreased cardiac output, and systemic hypotension. The pregnant woman is also predisposed to a more rapid decrease in arterial and venous oxygen tension during episodes of hypoxia. **These physiologic changes occurring to support the fetus complicate resuscitation efforts of the mother.**^{3,8,11,12}

In general, the same algorithms used for the nonpregnant patient should be used for the pregnant patient during cardiac arrest with some modifications.¹¹ The stroke volume of a term pregnant patient lying supine is only 30% of normal. Lateral displacement of the uterus will increase the stroke volume and cardiac output by at least 25%.¹³ Pregnancy increases the risk of aspiration. Early intubation to protect airway is indicated. Be cautious of using sodium bicarbonate to reverse metabolic acidosis. Rapid correction of maternal, but not fetal, acidosis could lead to reduced compensatory hyperventilation and normalization of fetal PaCO₂ with worsening of the fetal acidosis.⁸ The performance of adequate CPR in the gravid patient at or near term is extremely difficult. CPR produces a cardiac output equivalent to only 30% of normal under ideal circumstances. The enlarged uterus lies anterior to the inferior vena cava and suppresses venous return in the gravid patient. Uterine compression of the aorta increases afterload.

Consider early intubation. Oxygen consumption is higher in the pregnant patient due to an increased maternal metabolic rate plus the fetal demands. Functional residual capacity is lower. These factors lead to rapid hypoxemia. The patient's risk of aspiration is also higher due to decreased tone of the lower esophageal sphincter and delayed gastric emptying.⁸

The Emergency Physician must give early consideration to PMCD in the critically ill pregnant patient. Evacuation of the uterus will enhance maternal resuscitative efforts and may lead to higher rates of fetal survival as well.

INDICATIONS

The major indication for performing PMCD is to optimize maternal CPR. The rescue of a viable fetus greater than 20 weeks of gestation is an important consideration, but such rescue is always secondary

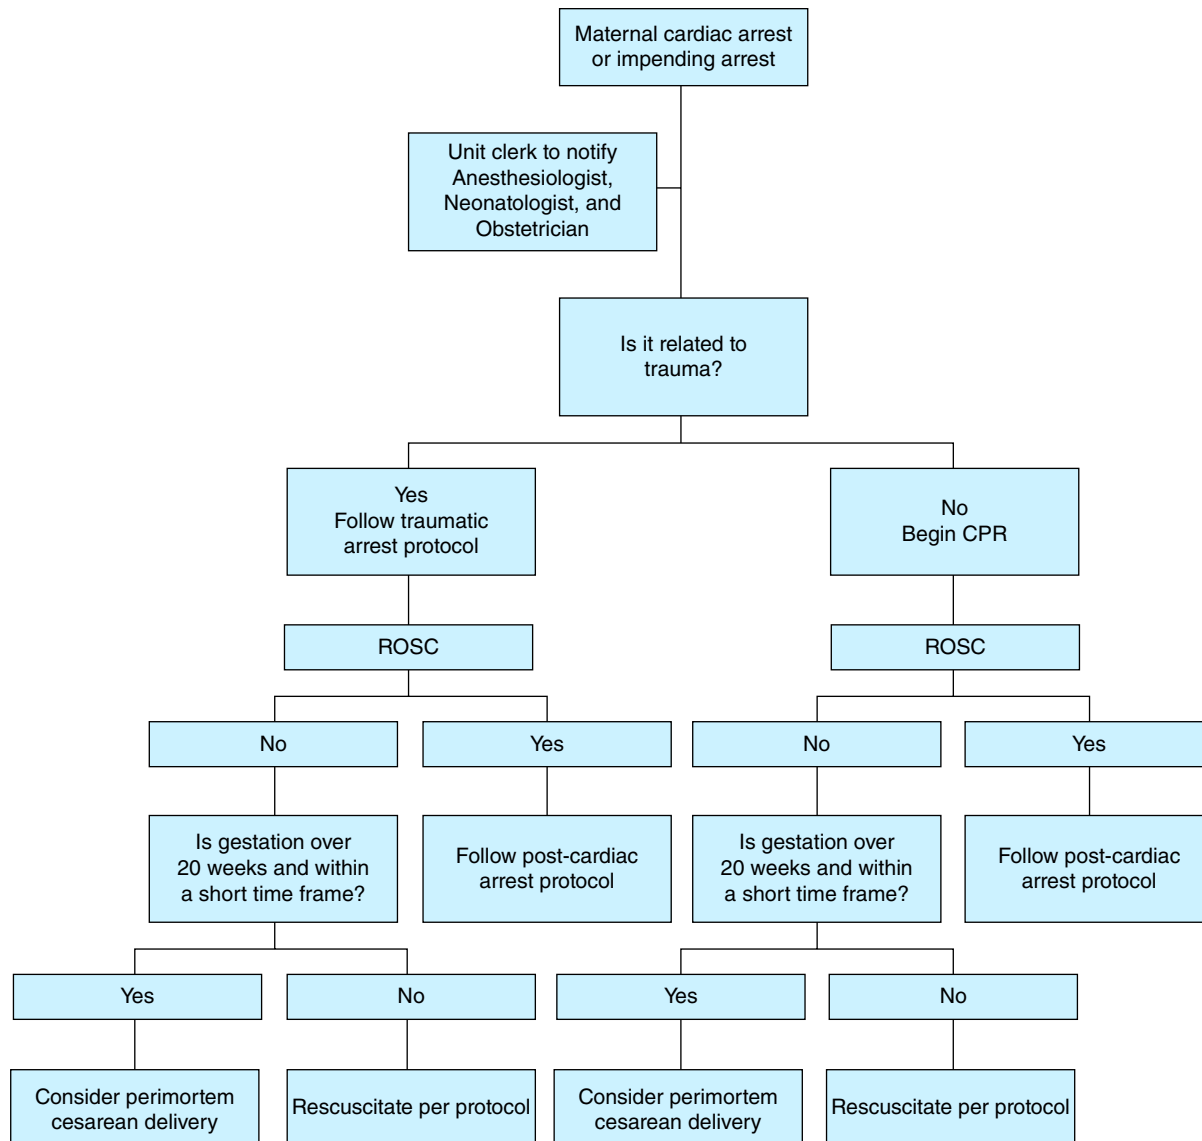

FIGURE 167-1. Algorithm for PMCD. (Modified from www.foamshed.wordpress.com/.)

to the safety and life of the mother. Consider performing PMCD if CPR does not lead to maternal ROSC within 4 minutes of her arrest.^{4,14-21} Waiting for the support of Obstetrical and Pediatric teams is contraindicated.^{2,13} Consider performing a PMCD, or having an Obstetrician perform it, for imminent maternal demise or as soon as CPR is begun.²² **Figure 167-1** provides an algorithm for performing a PMCD.

CONTRAINDICATIONS

There are few contraindications to performing a PMCD. The best fetal outcomes are reported when cesarean delivery is completed within 5 minutes of maternal arrest. However, a PMCD should be considered when the time from maternal arrest to delivery is no greater than 25 minutes.²³ It is contraindicated if the mother has a serious brain injury but is otherwise hemodynamically stable and the fetus shows no signs of distress. PMCD is contraindicated when the gestational age of the fetus is estimated to be less than 20 weeks.

Attempt to obtain consent for the procedure only if it does not introduce additional delay. There is no documentation of physician liability in these situations. The unanimous consensus in the medical literature and of legal authorities is that a civil suit for

performing a PMCD, regardless of the outcome, would not result in a judgment against the Emergency Physician.

EQUIPMENT

- 10 towel clips
- 16 Kelly clamps
- 16 hemostats
- 10 Peon or Pennington clamps
- 8 Allis forceps
- 6 Babcock forceps
- 6 ring forceps
- 6 straight Kocher clamps
- #10 surgical scalpel blade and handle
- #15 surgical scalpel blade and handle
- Straight Mayo scissors
- Curved Mayo scissors
- Metzenbaum scissors
- Bandage scissors

- Bladder retractor
- Pack of sponges
- Ring forceps
- Suture scissors
- 2 Adson forceps, or other forceps with teeth
- 2 Russian forceps, 5 1/2 inches and 8 inches
- Dressing forceps
- Skin stapler
- 2 medium Richardson retractors
- 2 small Richardson retractors
- 2 malleable retractors
- 2 Army-Navy retractors
- Needle drivers, 8 inches and 6 inches long
- 2 suction tips
- Suction tubing set(s)
- Wall suction
- Electrocautery unit with disposable tips
- Povidone iodine or chlorhexidine solution
- Sterile drapes
- Sterile gloves
- 2 skin staplers
- 3 packs 0 chromic suture with CTX taper needle
- 1 pack 2-0 chromic suture with taper SH needle
- 2 packs of 1-0 Vicryl suture with a CT taper needle
- Chromic, Polysorb, or Vicryl suture (2-0 or 1-0)
- Nylon suture, 3-0
- Bulb syringe
- Clean towels or blanket for baby
- Umbilical cord clamp
- Sterile scissors to trim umbilical cord
- Infant warmer
- Neonatal resuscitation kit
- Neonatal resuscitation equipment (including an infant warmer)

A lot of equipment is required to perform a PMCD. Ideally, all of the equipment required should be prepackaged in a sterile cesarean section instrument tray prepared by the hospital. A prepackaged sterile instrument tray is commercially produced but may not be available as this procedure is rarely performed in the Emergency Department. A standard thoracotomy tray or tube thoracostomy tray will contain all the required equipment except for the bulb syringe and umbilical cord clamp.

PATIENT PREPARATION

Quickly determine the gestational age using fundal height. A fundal height at the umbilicus correlates with a gestational age of approximately 20 weeks, at which time aortocaval compression by the uterus is likely to significantly hinder resuscitative efforts. A quick rule to remember is that if you can place at least four fingers above the umbilicus to the top of the fundus, the gestational age is likely to be equal to or more than 24 weeks.^{2,24} This estimate can be distorted by overweight patients, abdominal distention, and a history of multiple pregnancies. Unfortunately, no other quick rule has been yet described. If the mother has not yet arrested, bedside

ultrasound may be used to provide a more accurate estimation of gestational age.²⁵ **However, performance of the PMCD should never be delayed in order to obtain more accurate measurements or to assess for fetal heart tones.**

Note the time of maternal arrest and appoint a timekeeper. Maintain left uterine displacement (LUD) throughout the resuscitation. Plan to proceed with the PMCD if the resuscitation of a pregnant patient with an estimated gestational age of 20 weeks or greater has not regained spontaneous circulation within 4 minutes of her arrest.^{4,14-21}

The single most important prognostic factor for neonatal outcome is the time from maternal arrest to delivery. Delivery of the fetus can also maximize maternal resuscitation efforts and minimize the risk of maternal brain injury. Other resuscitative efforts, such as volume expansion and vasopressors, may be initiated simultaneously but should not delay the PMCD.

Time is of the essence. Establishing intravenous access and endotracheal intubation takes several minutes. Thus, it is very important to activate a protocol for a PMCD as soon as cardiac arrest occurs.^{12,13} Every attempt should be made to contact an Obstetrician and Neonatologist if PMCD is anticipated. Alert the covering General Surgeon if an Obstetrician is not available. Notify the neonatal resuscitation team of the impending procedure. Anesthesia will not be required if the patient is deceased. **The procedure should not be delayed in an attempt to obtain consent or the consultants.**^{1,12,26} The medicolegal risks are few since the Emergency Physician is acting under the principle of beneficence.

The patient will be clinically deceased in most cases if this procedure is performed in the Emergency Department. Patient preparation is not necessary and wastes valuable time when trying to salvage the fetus. Administer broad-spectrum intravenous antibiotics if the mother survives the procedure. Continue CPR throughout the PMCD.

LUD should be performed to reduce aortocaval compression. Stand on the patient's left side. Cup the uterus between two hands and lift it upward and leftward off the maternal vessels.^{22,27,28} **If the rescuer must be on the patient's right side, two hands are used to push the uterus upward and to the left.** LUD is preferred over maternal 15° lateral tilt maneuvers as the latter may lead to less effective chest compressions.²⁹ Prop the patient up if no assistant is available to maintain the patient in 15° of lateral displacement. This can be accomplished by putting pillows or blankets beneath the patient's right hip or with a Cardiff wedge. Lateral displacement of the uterus will increase maternal stroke volume and cardiac output by at least 25%.¹³

Surgical preparation in an emergency is minimal.^{1,26,30} Prepare the abdomen with povidone iodine or chlorhexidine solution. If time permits prior to maternal arrest, it is appropriate to employ the same sterile barrier methods as used during central line placement (i.e., a hat, mask, booties, sterile gloves, and a sterile gown). Have a nurse place a Foley catheter to drain the bladder and reduce the risk of bladder injury during the prearrest phase. Once the patient has become pulseless, bladder decompression is of minor importance and needle aspiration can always be performed by an assistant if a distended bladder interferes with the procedure.

TECHNIQUE

A long vertical incision is the most appropriate approach for this emergency procedure.³¹ It provides better exposure, easy access, and a larger opening for the delivery. Identify the patient's umbilicus and pubic symphysis. Make a long vertical midline skin incision with a #10 scalpel blade beginning at the top of the uterine fundus and

FIGURE 167-2. Accessing the peritoneal cavity. **A.** Make a midline skin incision from just below the umbilicus to just above the pubic symphysis. **B.** Extend the incision through the subcutaneous tissues and down to the linea alba. **C.** Grasp and elevate the rectus abdominis muscle while opening the linea alba with a Mayo scissors.

extending down to just above the pubic symphysis (**Figure 167-2A**). This incision is long enough to rapidly deliver a full-term infant.^{13,26,32} An alternative is to make the incision from just below the xiphoid process to the pubic symphysis. Ignore any subcutaneous bleeding unless it is arterial. Have an assistant clamp any bleeding arteries.

Extend the incision through the subcutaneous fat to the rectus sheath (**Figure 167-2B**). **Do not be overzealous and cut through the rectus sheath, peritoneum, uterus, abdominal organs, or bladder.** Grasp and elevate the rectus sheath using toothed forceps (**Figure 167-2C**). Make an incision in the rectus sheath with a Mayo scissors. Extend the rectus sheath incision superiorly and inferiorly with the Mayo scissors (**Figure 167-2C**). **Be cautious not to cut any abdominal or pelvic organs.**

Expose the uterus (**Figure 167-3**). The underlying peritoneal membrane (i.e., peritoneum) should be visible (**Figure 167-3A**). It may occasionally be attached to the rectus sheath and opened simultaneously. Instruct assistants to retract both sides of the rectus sheath laterally, or insert retractors if available, to fully expose the peritoneal membrane (**Figure 167-3A**). Grasp and elevate the peritoneal membrane with toothed forceps. Incise the peritoneal

membrane with a Mayo or Metzenbaum scissors in a manner similar to that used to open the rectus sheath (**Figure 167-3A**).³²

Make reasonable attempts to protect the bowel and bladder from injury. If possible, elevate the bowel off the field and cover it with a saline-soaked towel. Place a bladder retractor over the pubic symphysis to retract the rectus sheath and bladder (**Figure 167-4A**).³² Alternatively, grasp and elevate the bladder from the pelvis with a saline-soaked gauze or towel (**Figure 167-3B**). This will allow visualization of the uterus and prevent injury to the bladder.

Identify the position of the fetal head by palpating the uterus. **Carefully make a 2 to 4 cm midline vertical incision in the uterus with a #10 scalpel (Figure 167-4A).** The amniotic sac will bulge through the incision if the membranes are intact. **Place the index and/or middle fingers into the uterine cavity at the superior aspect of the incision to lift the uterine wall off of the fetus (Figure 167-4B).** Insert one blade of a bandage scissors and extend the uterine incision upward toward the fundus, cutting above the inserted finger(s) while lifting up on the uterine wall (**Figure 167-4B**). Repeat this procedure inferiorly to open the uterine wall in the direction of the bladder (**Figure 167-4C**).

FIGURE 167-3. Exposure of the uterus. **A.** Apply retractors to hold the abdominal wall open. Grasp, elevate, and incise the peritoneal membrane in the midline. **B.** Grasp and elevate the bladder out of the pelvis.

FIGURE 167-4. The vertical uterine incision. **A.** Make a 2 to 4 cm midline vertical incision with a scalpel blade. **B.** Place a finger into the incision to protect the fetus. Extend the uterine wall incision superiorly. **C.** Extension of the uterine wall incision inferiorly.

Rupture the amniotic membranes with a clamp or other blunt instrument. The placenta will often be embedded in the anterior wall of the uterus. It is imperative to expedite the delivery of the fetus by cutting through the placenta. Carefully transect the placenta. There is an urgency to deliver the fetus and clamp the umbilical cord to prevent significant fetal hemorrhage. Insert a hand between the pubic symphysis and the fetal occiput if the fetus is in a cephalic presentation (**Figure 167-5A**). Advance the hand to the base of the occiput. Gently flex the fetal head with the fingers and palm (**Figure 167-5A**). Apply gentle anteriorly and superiorly directed traction to elevate and deliver the head (**Figure 167-5B**). Deliver the entire fetal head

(**Figure 167-5C**). Consider suctioning the mouth and nose with a bulb syringe (**Figure 167-5D**).³² Deliver the shoulders in a manner similar to that of a vaginal delivery (**Figure 167-5E**). Apply gentle upward traction on the head while an assistant applies pressure on the uterine fundus. First deliver the anterior shoulder. Deliver the other shoulder followed by the torso and lower extremities. Once the shoulders are delivered, the remainder of the fetus readily follows.

If the fetus is in a breech presentation or transverse lie, feet first delivery is easiest. During the delivery, grasp the fetus by the pelvic bones and not by the abdomen to protect the delicate viscera.^{26,32} Deliver the fetus.

FIGURE 167-5. Delivery of the infant. **A.** Midsagittal section through the abdomen and pelvis. A hand is inserted between the pubic symphysis and the fetal head. **B.** Flex the fetal head while applying anterior and superior traction. **C.** Delivery of the entire fetal head. **D.** Suction the mouth and nose. **E.** Deliver the fetus while an assistant applies pressure to the uterine fundus.

FIGURE 167-6. Delivery of the placenta. **A.** Apply gentle upward traction on the umbilical cord while holding the uterine wall open. **B.** Insert a hand between the placenta and the uterine wall to separate the placenta from the uterus.

Clamp the umbilical cord with a hemostat or umbilical cord clamp approximately 10 cm from the fetus. Attach a second hemostat or clamp 2 to 3 cm distal to the first. Cut the umbilical cord between the clamps with a scissors. Hand the neonate to waiting personnel for resuscitation.^{7,26,32} Resuscitate the neonate yourself if additional help is not available.

AFTERCARE

Palpate inside the uterus for another fetus to rule out an unknown twin pregnancy. Deliver the placenta (**Figure 167-6**). Apply gentle upward traction on the umbilical cord while holding the uterine wall open (**Figure 167-6A**). Insert the other hand between the placenta and uterine wall (**Figure 167-6B**). Apply gentle pressure to separate the placenta from the uterus and sweep the uterus clean. Begin an oxytocin infusion of 20 U in 1 L of normal saline at a rate of 10 mL/min to help the uterus contract if the mother shows signs of life.³²

Close the patient if they are still alive or if they regain vital signs. Apply ring forceps to the uterine incision. Close the uterus in two layers with 0 or 1-0 absorbable chromic gut, Polysorb, or Vicryl suture. Close the first layer in a running locked fashion (**Figure 167-7A**). This will provide hemostasis. A second running layer is necessary to ensure hemostasis and reapproximate the uterine wall. Closure of

the serosa of the uterus (**Figure 167-7B**) and the peritoneal membrane (**Figure 167-7C**) is recommended but not required. Close the serosa and peritoneum with running 2-0 absorbable chromic gut, Polysorb, or Vicryl suture. Identify and grasp the cut ends of the rectus sheath with hemostats. Close the rectus sheath in a running pattern with 2-0 absorbable suture (**Figure 167-7D**). Close the skin with running 3-0 nylon (**Figure 167-7E**) or staples for speed.^{13,26,32}

The only closure required if there is no hope of maternal ROSC is a minimal closure of the skin. Use either a running baseball stitch or skin staples.

COMPLICATIONS

The major complications associated with PMCD include maternal sepsis, maternal visceral injury, maternal hemorrhage, and fetal injury secondary to delivery.³³ The possible benefits of maternal and/or fetal survival far outweigh these considerations.¹

SUMMARY

The perimortem cesarean section or delivery is an emergency procedure that should be considered in any maternal arrest with an estimated fetal gestational age of 20 weeks or greater. This is a high-stress

FIGURE 167-7. Closure of the incisions. **A.** Running locked closure of the uterine wall. **B.** Closure of the serosa of the uterus. **C.** Running closure of the peritoneal membrane. **D.** Running closure of the rectus sheath. **E.** Running closure of the skin.

procedure requiring fast decision making. Emergent delivery of the fetus may provide the mother with her greatest chance of survival. It also provides the fetus with a chance for survival in the face of maternal death. The medicolegal risks are few. Whenever possible, it should be completed by minute 5 after maternal arrest, timing that confers the greatest potential for maternal and fetal survival.

Symphysiotomy

Ikem Ajaelo

INTRODUCTION

Symphysiotomy is the artificial division and separation of the pubic symphysis to facilitate vaginal delivery. This is not to be confused with a pubiotomy or the severance of the pubic bone a few centimeters lateral to the symphysis for the same purpose. A symphysiotomy was first performed in the seventeenth century. It is indicated in cases of cephalopelvic disproportion and may be a lifesaving alternative to cesarean delivery.¹⁻⁵ The reported success rate of this procedure is approximately 80% when performed appropriately.⁶

The procedure requires minimal equipment and can be accomplished under local anesthesia in as little as 2 to 3 minutes.^{6,7} The increased availability of cesarean sections combined with the known urologic and orthopedic complications have led to its decline and lack of acceptance in modern obstetrical practice.^{8,9} However, symphysiotomies are performed regularly and successfully in developing countries where resources and trained medical professionals are often limited or unavailable.^{2,3,10}

Indications for a symphysiotomy include breech delivery, cephalopelvic disproportion, and relief of shoulder dystocia.^{1,11,12} Each of these conditions poses significant potential risks to mother and child, even under optimal conditions. Emergency Physicians should be familiar with the indications and technique of symphysiotomy as expeditious delivery is vital in these scenarios.

ANATOMY AND PATHOPHYSIOLOGY

The pelvis is composed of four bones: the sacrum, the coccyx, and the innominate bones. Each innominate bone is made up of the fused ischium, ilium, and pubis. The innominate bones are connected at the sacrum by the sacroiliac ligaments and at the pubic symphysis by the superior and arcuate pubic ligaments.¹² Together they determine the size and shape of the pelvis. The fetus assumes positions during labor that are primarily determined by the conformation of the mother's pelvis.¹³

The pelvis is divided into a true pelvis and a false pelvis. They are separated by the linea terminalis, an anatomic boundary formed by the pelvic brim (i.e., superior pelvic aperture). The true pelvis lies below the linea terminalis and is the more relevant portion in delivery.¹⁴ Dense ligaments hold the walls of the true pelvis together. The posterior wall is the anterior surface of the sacrum and coccyx. The lateral boundaries are formed by the inner surface of the ischial bones as well as the sacrospinous notches and ligaments. The ischial spines can be readily palpated during the vaginal or rectal

examination. They serve as important landmarks in determining to which level the presenting part has descended into the true pelvis. The true pelvis is bounded anteriorly by the pubic bones, the ascending superior rami of the ischial bones, and the obturator foramina.

The ligaments of the pubic symphysis and the sacroiliac ligaments allow mobility and contribute to the increase in pelvic diameter during pregnancy.¹³ The sacral nerves, the coccygeal nerves, and the pelvic portion of the autonomic nervous system innervate the pelvis. The important pudendal nerve arises from the sacral plexus and accompanies the internal pudendal artery. It enters the perineal region via the lesser sciatic foramen and around the sacrospinous ligament to supply the muscles of the perineum.¹² Anesthesia to the perineal region can be accomplished by performing a pudendal nerve block.

INDICATIONS

Symphysiotomy is indicated in any difficult delivery in the presence of fetal distress or obstructed labor or when an Obstetrician is not immediately available.¹⁻³ It has traditionally been reserved for complicated breech deliveries. It has also been reserved for cases of cephalopelvic disproportion in which the fetal head is presenting vertex, at least one-third of the fetal head has entered the pelvic brim, and cervical dilatation is no more than 7 cm.¹ Symphysiotomy has been advocated more recently for the relief of intractable shoulder dystocia.^{11,15}

CONTRAINDICATIONS

Contraindications to performing a symphysiotomy include fetal demise and incomplete dilatation of the cervix.⁸ Some authors have recommended limiting symphysiotomy to mothers weighing between 50 and 80 kg and a fetus with an estimated mass of 2700 to 3700 gm.^{15,16} Other relative contraindications include the presence of maternal spinal deformities, hip deformities, pelvic deformities, and gross obesity.¹⁵ Symphysiotomy has been performed after a prior cesarean section without added complications despite concerns regarding the safety of symphysiotomy in the presence of a previous cesarean scar.¹⁵

EQUIPMENT

- Local anesthetic solution
- Povidone iodine or chlorhexidine solution
- Sterile gloves and gown
- Face mask and cap
- Urethral catheter set
- Sterile drapes
- #10 scalpel blade on a handle
- Mayo scissors
- Finger guard
- Hemostats
- Sterile gloves
- Neonatal resuscitation equipment
- Infant warmer

PATIENT PREPARATION

Explain the risks, benefits, and potential complications to the patient and/or their representative. Obtain an informed consent to perform this procedure if time allows. Place the patient in the lithotomy position with their thighs separated no more than 90°. This position is

necessary to prevent undue strain on the sacroiliac joints. Two assistants should be available to maintain proper maternal leg positioning. Insert a Foley catheter to drain the bladder (Chapter 173).

Prepare the surgical area. Shaving the mons pubis is optional. Apply povidone iodine or chlorhexidine solution onto the skin overlying the pubic symphysis and surrounding area. Allow this to dry. **The Emergency Physician must perform this procedure using aseptic technique.** This includes wearing sterile gloves, a sterile gown, a cap, and a face mask. Apply sterile drapes to form a sterile field. Infiltrate the anterior and inferior aspects of the pubic symphysis and the surrounding skin with 5 to 10 mL of local anesthetic solution to anesthetize the pubic symphysis. Leaving the needle in place may be useful in identifying the pubic symphysis joint. Equipment for infant resuscitation should be readily available, as with all deliveries. Notify the neonatal resuscitation team and a Neonatologist of the impending procedure and delivery.

TECHNIQUE

Apply the finger guard to the nondominant index finger. Place the nondominant index finger into the vagina and against the posterior aspect of the pubic symphysis (**Figure 168-1**). Advance the finger approximately 2 to 3 cm beyond the superior aspect of the pubic symphysis to displace the bladder and urethra. **Do not move this finger until the procedure is complete.**

Grasp the scalpel in the dominant hand with the cutting edge of the blade facing outward (**Figure 168-2**). **The scalpel blade must be kept in a strict midsagittal plane and perpendicular to the skin overlying the pubic symphysis.** Resting the hypothenar eminence of the dominant hand against the patient's pubic ramus will help maintain fine control of hand and finger movements.⁶

Make a midline stab incision 1 cm below the upper edge of the pubic symphysis (**Figure 168-3**). **Very little resistance should be met as the scalpel blade pierces the hyaline cartilage of the pubic symphysis if the scalpel is in the midline.** Carefully and slowly advance the scalpel blade until the tip is just felt through the anterior vaginal wall. Resistance is usually a result of lateral deviation of the scalpel blade against the pubic bones. Withdraw the scalpel blade 2 to 3 mm and readvance it in the midline. **Use extreme caution so that the scalpel does not lacerate the vagina, the urethra, or the finger.**

FIGURE 168-1. Frontal view demonstrating the nondominant index finger inserted into the vagina and pushing anteriorly to palpate the pubic symphysis.

FIGURE 168-2. Skeletal outline demonstrating the position of the scalpel blade in relation to the pubic symphysis.

Lower the handle of the scalpel blade cephalad, toward the abdomen, using the upper portion of the pubic symphysis as a fulcrum. Cut through the lower half of the pubic symphysis dividing the cartilage and associated ligaments. Remove the scalpel blade and reinsert it with the cutting edge in the opposite direction and facing cephalad. Repeat the same maneuver but with the scalpel handle lowered caudally to divide the upper portion of the pubic symphysis and completing the separation.

Use the nondominant index finger to confirm complete separation of the pubic symphysis. **The symphysiotomy is complete when**

FIGURE 168-3. Sagittal view of a symphysiotomy using the scalpel blade to divide the pubic symphysis.

the index finger pressing through the vaginal wall can fit into the space between the pubic symphysis. Reinsert the scalpel to complete the division if any ligaments or cartilage remains. The entire procedure should take 2 to 3 minutes. A variation of the above technique involves simply dividing the pubic symphysis in a single step by a repeated slow stabbing motion.

Delivery of the infant should follow once the symphysiotomy is completed. Delivery of the infant usually requires more downward traction than is usually necessary.

AFTERCARE

Deliver the placenta and control any postpartum hemorrhage. Carefully return the mother to the supine position with their thighs in normal anatomic position. Close the skin and subcutaneous tissue with simple interrupted 4–0 nylon sutures. Some authors have recommended binding the knees for 12 to 48 hours to prevent inadvertent abduction or external rotation of the hips.¹⁷ Admit the patient to the hospital for observation and monitoring of any potential complications. Leave the Foley catheter in place until any bleeding resolves or the patient begins to walk. Patients may begin ambulation with assistance between the second and fifth days. They should be warned against any unusual straining or heavy lifting.

COMPLICATIONS

Experience and careful case selection appear to be the most important factors in determining outcome and morbidity associated with this procedure.⁶ Symphysiotomies do not cause maternal death. Immediate complications include bladder lacerations, urethral lacerations, subcutaneous bleeding, and urinary incontinence.^{15,17} Some patients develop gait instability immediately after the operation that tends to be transient and does not appear to affect subsequent pelvic stability.¹⁸

Lacerations to the Emergency Physician's fingers are a significant concern.^{19,20} Prevent lacerations by using the utmost of care and slowly transecting the cartilage and ligaments of the pubic symphysis. The nondominant hand should be double-gloved at a minimum.¹⁹ The use of a Kevlar glove that is resistant to scalpel injury may also be used.²⁰ A third option is to apply a malleable splint over the palmar aspect of the index finger before double gloving.¹⁹ A final option is to use a finger guard.

Long-term complications include, but are not limited to, stress urinary incontinence, recurrent urinary tract infections, sepsis, and vesicovaginal fistulas.²¹ Vaginal fistulas are frequently due to nonplacement of a Foley catheter during the procedure.⁸ **This important step should never be omitted.** The effect of a symphysiotomy on subsequent pregnancies has not been studied in detail. The limited data available suggest that a symphysiotomy permanently enlarges the pelvis so that subsequent vaginal deliveries are easier.^{3,18} Late-onset osteoarthritis of the sacroiliac joints is possible.²²

SUMMARY

Modern surgical techniques and obstetrical advances have diminished the practice of a symphysiotomy.⁹ The symphysiotomy still remains a simple and safe method to overcome the common and lethal problems of cephalopelvic disproportion, shoulder dystocia, and breech deliveries when an Obstetrician is unavailable or in a resource-limited setting.^{2,3,15} The procedure itself can be mastered by any clinician responsible for the care of a woman in active labor.¹⁹ A symphysiotomy is a viable and potentially lifesaving option for anyone who may be working outside the confines of a well-staffed and equipped hospital.

Bartholin Gland Abscess or Cyst Incision and Drainage

Alison Uyemura and Charlie C. Kilpatrick

INTRODUCTION

Bartholin gland cysts and abscesses are common problems for women of reproductive age with an incidence of 2% in this population.¹⁻⁴ A Bartholin gland and its duct may enlarge to form a Bartholin cyst or become infected to form a Bartholin abscess. A number of different techniques have been developed for the treatment of Bartholin cysts and abscesses.

ANATOMY AND PATHOPHYSIOLOGY

The Bartholin glands are named after Caspar Bartholin, a Danish anatomist.^{1,5} They are located on each side of the vulvar vestibule beneath the fascia, posterolaterally to the vaginal orifice, and at the

4 and 8 o'clock positions.^{6,7} The glands are approximately 1 cm in diameter, the size of a pea, and drain through a duct approximately 2.5 cm in length. The ducts of the glands open into the vulvar vestibule at the 5 and 7 o'clock positions, existing between the hymenal ring and the labia minora. The cells of the gland produce mucin which is secreted during sexual excitement and contributes to vaginal lubrication.^{5,8} The Bartholin glands are not normally palpable. The gland has an extensive blood supply from branches of the internal pudendal artery. The neural supply is provided from branches of the pudendal nerve.

A cyst of the Bartholin gland may develop most often secondary to obstruction of the duct. This leads to ductal dilation and cyst formation. Noninfectious etiologies of cyst formation include inspissated gland secretions, trauma, tumors of the vulva, or scarring of the duct from repeated bouts of cyst formation.³ Cysts may grow as large as 3 cm. Bartholin cysts present as painless unilateral swellings in the labial area. A patient will become symptomatic if they become large enough or infected. Infected cysts contain purulent material and are known as a Bartholin abscess, although it is more akin to a pseudoabscess unless the surrounding tissue appears erythematous, tender, and inflamed.³ A Bartholin cyst may present with pain, dyspareunia, pressure, difficulty with walking, or may be completely asymptomatic.^{5,8-12} The diagnosis is made on visual inspection of the vulva. Common signs are a mass near the inferior labia minora, drainage, and erythema.

Primary carcinoma of the Bartholin gland is a rare occurrence but should be considered in the differential diagnosis. Most cancers occurring in the Bartholin gland are metastatic primary vulvar cancers. They can present as a Bartholin gland cyst when the vulvar cancer obstructs the ductal outflow of the gland. Adenocarcinoma (40%), squamous cell carcinoma (40%), adenoid cystic carcinoma (15%), and transitional cell carcinoma (5%) of the Bartholin gland have all been documented.^{7,13-20} Carcinoma can easily mimic a Bartholin gland cyst or abscess.

The majority of Bartholin gland cysts appear to be sterile or contain bacteria common to the vaginal flora.²¹⁻²³ Studies of Bartholin gland abscesses have shown no bacterial growth in up to 30% of specimens cultured.²³⁻²⁵ The causative organisms are multiple in the cultures that do grow bacteria. The most prevalent organisms isolated are anaerobes, with *Bacteroides* and *Peptostreptococcus* being the most common species.²⁴ The remainder of the cultures demonstrated either aerobic/facultative isolates, with *Escherichia coli* being the most common species, or a mixture of both aerobic and anaerobic organisms.²² *Neisseria gonorrhea* and *Chlamydia trachomatis* have also been implicated as causative agents and have been isolated in up to 16% of cultures.^{23,26}

INDICATIONS

Small and asymptomatic cysts in women less than 40 years of age can be managed expectantly. All others should be treated. Any cyst that becomes large and symptomatic (e.g., painful, interfering with physical or sexual activity, or interfering with the flow of urine) should be treated. Any cyst that appears tender, red, hot, or cellulitic represents a Bartholin abscess and requires treatment.

CONTRAINDICATIONS

There is some controversy about the treatment of Bartholin cysts and abscesses in women over the age of 40. Previously, the recommendation was to excise the gland in women over the age of 40 for concern of the possibility of carcinoma. Carcinoma of the Bartholin gland is rare, comprising less than 1% of female genital tract neoplasms.¹² It is felt that women over the age of 40 are at an increased risk for having carcinoma of the Bartholin gland, Bartholin duct, or

adjacent structures; and thus all of these should be properly biopsied or completely excised and sent for pathologic evaluation.^{1,7,8,13-15} Another study reported an incidence of Bartholin gland cancer in postmenopausal women of 0.114 per 100,000 women and suggests that selective biopsy be performed to reduce the number of total excisions.¹⁶ Given the rarity of malignancies in this area, this view has been challenged in the recent literature. Currently, drainage and selective biopsy seems to be a reasonable alternative.⁸ In general, these women should be referred to a Gynecologist for diagnosis and further treatment.

Patients who have had multiple recurrences and previous treatments are best served with a referral to their Gynecologist for more definitive measures.

Consider draining Bartholin abscesses that are large or extremely tender in the Operating Room. Other indications for drainage in the Operating Room include patients with a contraindication to procedural sedation, those who cannot be adequately anesthetized using procedural sedation and local anesthetics, and those who cannot be safely sedated in the Emergency Department.

EQUIPMENT

■ SIMPLE INCISION AND DRAINAGE

- Povidone iodine or chlorhexidine solution
- Gloves and gown
- Face mask with an eye shield or goggles
- Drapes
- Lidocaine, 1% or 2%
- 3 mL syringe
- 18, 24, and 25 gauge needles
- Gauze squares, 2×2 and 4×4
- #11 scalpel blade and scalpel handle
- Culture medium for routine bacteria, gonorrhea, and chlamydia
- Hemostat
- Small wick, 2 inches long

■ INCISION AND INSERTION OF A WORD CATHETER

- Equipment for simple incision and drainage
- Word catheter
- 5 mL sterile saline or water

■ MARSUPIALIZATION

- Equipment for simple incision and drainage
- 2 small retractors
- Specimen container for excised tissue
- Silver nitrate sticks or electrocautery
- Vicryl, 3-0 or 4-0 on a cutting needle
- Scissors
- Small toothed forceps

■ WINDOW OPERATION

- Same as equipment for marsupialization

PATIENT PREPARATION

Explain the risks, benefits, and potential complications of the procedure to the patient and/or their representative. The postprocedural care should also be discussed. Obtain a signed consent for

the procedure. Some Emergency Physicians may omit the signed consent and place in the procedure note a statement saying: "The risks, benefits, and complications were described and discussed with the patient. They understood this and gave verbal consent for the procedure."

Place the patient in the lithotomy position. Apply povidone iodine or chlorhexidine solution to the labia and allow it to dry. **The surface of the vagina must be anesthetized as the procedure is extremely painful.** The use of ice packs, topical refrigerant spray (Chapter 154), parenteral sedation, parenteral analgesics, or procedural sedation (Chapter 159) should be considered for patient comfort prior to infiltrating local anesthetic solution. Infiltrate 0.25 to 1.0 mL of local anesthetic solution subcutaneously under the mucosal surface of the labia minora for simple incision and drainage with or without the use of a Word Catheter. When injecting local anesthetics, ensure that you do not inject purulent material after aspiration as this can cause extensive inflammation. Infiltrate 2 to 3 mL of local anesthetic solution if a marsupialization will be performed.

The Emergency Physician should be wearing a gown, gloves, and a face mask with an eye shield or goggles. The cyst contents are usually under pressure and can spray out. A face mask and eye protection will prevent a mucous membrane exposure if the contents spray out of the incision. The gown will protect clothing from contamination.

TECHNIQUES

A number of different treatments and procedures have been developed to manage a Bartholin cyst or abscess.^{4,20} These are largely influenced by its size, patient symptoms, the age of the patient, the suspected etiology, and any previous treatment in the same patient. The techniques include simple incision and drainage, incision and insertion of a Word catheter, marsupialization, a window operation, and complete excision.

SIMPLE INCISION AND DRAINAGE

The standard treatment for most abscesses is simple incision and drainage.^{8,10,11,27,28} Simple incision and drainage of a Bartholin cyst or abscess provides immediate pain relief but is often complicated by chronic recurrences. This technique is not recommended but described for the sake of completeness.

Spread open the labia to visualize the area (**Figures 169-1A and 169-1B**). Make a 1 cm vertical incision on the mucosal surface of the labia minora in the vaginal vestibule. It should be parallel to the border of the hymenal ring, between the hymen and labia minora (**Figure 169-1**). **The incision should ideally be external to the hymenal ring, if possible, and in the area where the duct normally exits.** Extend the incision into the abscess/cyst cavity. **Do not make incisions along the skin surface of the labia minora.** Skin incisions along the labia minora can lead to the formation of a fistula tract, more postprocedural pain, and are fraught with complications. Culture the contents of the sac. Manually express the contents of the sac. Insert a hemostat and break any adhesions. There is no need to irrigate the cavity as this will cause additional pain for the patient and does not affect the outcome.²⁹ Place a small wick within the cavity and exiting the incision to allow for complete drainage and prevent premature closure of the skin incision.

INCISION AND INSERTION OF A WORD CATHETER

Dr. B. Word first described this procedure in 1964.⁵ It is a relatively simple procedure that can be accomplished in the Emergency Department.^{5,8,10,11,30} The catheter is approximately 5 cm long and

A

B

FIGURE 169-1. Simple incision and drainage of a Bartholin cyst or abscess. Spread open the labia to expose the area. **A.** The dotted line represents the incision line over the cyst or abscess. **B.** Scalpel incision results in a purulent fluid. (Used with permission from Knoop KJ, Stack LB, Storrow AB, Thurman RJ (eds): *The Atlas of Emergency Medicine*, 4th ed. New York: McGraw-Hill, 2016. Photo contributor: Medical Photography Department, Naval Medical Center, San Diego, CA.)

made of soft pliable latex with a 10 French tip. The tip contains a balloon that inflates up to a volume of 5 mL (**Figure 169-2**). These catheters cost approximately \$15 each (Berkeley Medevics Inc., Berkeley, CA).

Verify that the patient is not allergic to latex.⁹ Fill a 5 mL syringe armed with a 24 or 25 gauge needle with saline or water. Insert the

FIGURE 169-2. The Word catheter. The plastic catheter has a port at its proximal end to insert a needle. The distal end contains a balloon that can be inflated.

needle into the self-sealing port on the distal end of the Word catheter. Inject 3 to 4 mL of the fluid to inflate the balloon. Observe the balloon for any leaks. If no leaks are visible, aspirate the fluid back into the syringe to deflate the balloon. Remove the needle from the self-sealing port.

Spread open the labia to completely visualize the area (**Figure 169-3A**). Make a 0.5 cm long puncture on the mucosal surface of the vulvar vestibule with a #11 scalpel blade into the cyst or abscess cavity (**Figure 169-3A**). **This puncture should ideally be located just outside the hymenal ring and where the duct normally drains into the vulvar vestibule, between the hymen and labia minora at the 5 or 7 o'clock position.** The incision should be just large enough to allow the passage of the Word catheter. Culture the contents of the sac. Manually express the contents of the sac. Insert a small hemostat and break any adhesions. There is no need to irrigate the cavity as this will cause additional pain for the patient and does not affect the outcome.²⁹

Insert the tip of the Word catheter deep within the cavity (**Figure 169-3B**). Inject 2 to 4 mL of sterile saline into the free end of the catheter to inflate the balloon (**Figures 169-3C and 169-4**). **Pain upon inflation of the balloon or persistent pain after the procedure indicates overinflation of the balloon. Do not use air to inflate the balloon.** The catheter will stay in place because the inflated balloon is larger than the puncture incision. Tuck the free

C

FIGURE 169-3. Incision and insertion of the Word catheter. **A.** Make a 0.5 cm long stab incision on the mucosal surface of the labia minora. **B.** The cavity has been evacuated and the Word catheter inserted. **C.** The balloon is inflated with saline.

FIGURE 169-4. The Word catheter is inserted and inflated with saline. (Used with permission from Knoop KJ, Stack LB, Storrow AB, Thurman RJ (eds): *The Atlas of Emergency Medicine*, 4th ed. New York: McGraw-Hill, 2016. (Photo contributor: Medical Photography Department, Naval Medical Center, San Diego, CA.)

end of the catheter within the vaginal canal. The Word catheter should ideally stay in place for up to 4 weeks. This allows the tract to become epithelialized and prevent a recurrence. The patient should abstain from sexual activity while the catheter is in place.

MARSUPIALIZATION

Marsupialization is an alternative treatment choice initially described in 1950.^{1,8,10,11,28,31-34} It is performed once and, in some case series, has been shown to be curative in greater than 90% of patients.^{33,35} Advantages are that it can be done as an outpatient, is associated with little postoperative pain, has minimal postoperative scarring, and preserves the gland function.⁹ Marsupialization can be easily and safely performed in the Emergency Department using local anesthesia. **Do not attempt to marsupialize a Bartholin abscess with an accompanying cellulitis.** Some Obstetricians prefer to perform this procedure in the Operating Room under general anesthesia.

Make an oval-shaped or elliptical incision approximately 1.5 cm long and 1 cm wide through the vestibular mucosa over the cyst/abscess and just outside the hymenal ring (**Figure 169-5A**). Remove this piece of mucosa to visualize the anterior wall of the cyst/abscess cavity. Insert a retractor to pull the skin edges open and better visualize the sac (**Figure 169-5B**). Make a similar incision through the anterior wall of the cyst/abscess cavity (**Figure 169-5B**). Most times

the initial incision will pierce both the vaginal mucosa and cyst wall. Remove this piece of tissue, leaving the cavity exposed. Culture the contents of the sac. Express the contents of the sac. Insert a small hemostat and break any adhesions. There is no need to irrigate the cavity as this will cause additional pain for the patient and does not affect the outcome.²⁹

Control any bleeding with electrocautery, silver nitrate application, or manual pressure. Closing the cavity with interrupted sutures, as a final option, will control the bleeding. Suture closure is only temporary for hemostasis as this pocket will become reinfected and require another procedure. Remove any sutures placed for hemostasis in 20 to 30 minutes. Identify the former bleeding site and treat it with electrocautery or silver nitrate to prevent rebleeding after the patient leaves the Emergency Department.

Evert the cyst/abscess wall. Approximate the wall of the cyst/abscess to the vestibular mucosa. Sew the wall of the cavity to the mucosa of the vulvar vestibule with interrupted 3-0 or 4-0 Vicryl sutures (**Figure 169-5C**). The orifice will reduce in size, epithelialize, and form a new duct in time. **Send all excised tissue to the Pathology Department to confirm the diagnosis and to rule out neoplasm.**^{18,19}

WINDOW OPERATION

This technique is almost identical to marsupialization.³⁶ It differs only in the size of the incision. One study claimed this procedure had no long-term complications or recurrences thus making it a more desirable technique.³⁶ However, the total patient population was small and the study has not been duplicated and republished. In essence, one follows the exact procedure for marsupialization with the exception of making a larger incision (2 to 3 cm long and 1.5 cm wide). At the completion of the procedure, a wide opening is observed. The opening will be approximately one-half its original size at the 1 year follow-up. This much larger and radical incision is not recommended for the Emergency Physician.

COMPLETE EXCISION

This technique is reserved for the treatment of recurrent cysts and abscesses unresponsive to less invasive techniques.^{8,10-13,16,28,36} It is also indicated for patients in whom carcinoma is suspected. Even though the function of the gland is to provide lubrication for sexual activity, in a well-estrogenized woman removal of the gland poses

FIGURE 169-5. The marsupialization of a Bartholin cyst or abscess. **A.** An elliptical incision, 1.5 cm in length and 1.0 cm in width, is made through the vulvar mucosa and just outside the hymenal ring. The ellipse of mucosal tissue is then removed. **B.** An elliptical incision (dotted line) is then made through the anterior wall of the cyst or abscess. **C.** Approximation of the cyst or abscess wall to the vestibular mucosa with 3-0 or 4-0 interrupted Vicryl suture.

little clinical problem. In the past, excision of the Bartholin gland in all women over the age of 40 for fear of carcinoma was championed. This has been challenged given the low incidence of carcinoma of the Bartholin gland in favor of drainage and selective biopsy.⁸ Significant bleeding may complicate dissection into this area due to the underlying anastomosing venous plexus. If hemostasis is not achieved, a vulvar hematoma will result. Excision of the gland is often referred to as the “bloodiest little operation in gynecology.” This procedure should only be performed by a Gynecologist in the controlled setting of an Operating Room under general anesthesia.

ALTERNATIVE TECHNIQUE

An alternative to the Word catheter has been described in the literature.³⁷⁻³⁹ The advantages of this technique are that the materials are available in every Emergency Department, the device does not prematurely fall out as often happens with the Word catheter, and it is easily placed. Unfortunately, these reports had few patients. Larger studies comparing this technique to the Word catheter are required.

Prepare the equipment. Obtain a 5 to 7 cm long piece of tubing. Suggestions include cutting a piece from an 8 French T-tube or a butterfly intravenous catheter.³⁷⁻³⁹ Insert a strand of 2-0 silk suture, without a needle or the needle cut off, through the tubing (**Figure 169-6A**).

The procedure is quite similar to that previously described. Make a stab incision in the lower half of the abscess and outside the hymenal ring with a #11 scalpel blade (**Figure 169-6B**). Insert a hemostat and break any loculations (**Figure 169-6C**). With the hemostat in the abscess cavity for support, make a second stab incision in the upper half of the abscess (**Figure 169-6D**). Insert one end of the silk suture into the upper or second incision and grasp it with the hemostat (**Figure 169-6E**). Pull the suture and tubing out through the first or lower incision (**Figure 169-6F**). Tie the ends of the suture to form a ring with the tubing (**Figure 169-6G**). Place four to five knots in the suture. Cut off the excess suture.

AFTERCARE

All abscess and cyst contents should be cultured. The initiation of antibiotics can be delayed pending the culture results at the discretion of the physician. Administer antibiotics if the abscess is accompanied by cellulitis. Keep in mind the prevalence of methicillin-resistant *Staphylococcus aureus* (MRSA) in soft tissue infections and specifically in labial abscesses when choosing antibiotics.⁴⁰⁻⁴²

All patients should begin sitz baths in 2 days. Prescribe appropriate oral analgesics. Nonsteroidal anti-inflammatory drugs will provide most patients with adequate analgesia. Some patients may

FIGURE 169-6. An alternative technique to incise and drain a Bartholin cyst or abscess. **A.** A silk suture has been inserted through the tubing. **B.** A stab incision is made in the lower half of the abscess and outside the hymenal ring. **C.** A hemostat is inserted to break any loculations. **D.** The hemostat provides support as a second stab incision is made in the upper half of the abscess. **E.** One end of the silk suture is grasped with the hemostat. **F.** The suture and tubing are pulled out through the lower incision. **G.** The suture ends are tied to form a ring with the tubing.

require a brief course (1 to 3 days) of narcotic analgesics. Give written discharge instructions to each patient explaining the aftercare, the complications, and the actions to take if a complication does arise. All patients should abstain from sexual activity until the inflammation and pain resolve or until the Word catheter is removed.⁴³

COMPLICATIONS

The most common complication with the incision and drainage technique is frequent recurrence. The most common complication of Word catheter insertion is premature loss of the catheter resulting in early incision closure and recurrence. This can be due to a large incision, underinflation of the balloon, injection through or piercing with the needle other than the injection site, or more than two needle punctures to the injection port. The Word catheter can also be associated with significant discomfort if the catheter is inserted improperly. Marsupialization has few complications and a low recurrence rate. With any of these procedures, one can miss a carcinoma of the Bartholin duct or Bartholin gland if a biopsy or excision is not performed. Bleeding and progressive infection, including sepsis and toxic shock syndrome, are rare but possible complications.^{44,45}

The immunocompromised patient (e.g., diabetic, steroid dependent, or human immunodeficiency virus positive) needs particular attention paid to cleanliness during and after the procedure. If the abscess is accompanied by cellulitis and/or involves the labia majora, consider inpatient management and gynecologic consultation. Initial intravenous antibiotics should cover MRSA. A large Bartholin/labial abscess in a diabetic patient requires close surveillance and a high suspicion for necrotizing fasciitis. Daily follow-up visits are recommended for these patients during the initial postprocedural period. Early hospitalization and administration of intravenous antibiotics are warranted if there is any sign of progressive infection.

SUMMARY

Bartholin cysts and abscesses will be encountered by the Emergency Physician and can easily be treated. They present as a painful unilateral swelling of the inferior aspect of the labia. There are many treatment options. Culture all cyst or abscess contents. Send any tissue removed to the Pathology Department to rule out carcinoma. Refer patients with previously treated cysts or abscesses, those suspicious for carcinoma, and those over the age of 40 to a Gynecologist for definitive care. Give all patients written discharge instructions at the end of the procedure. All immunocompromised patients require very careful follow-up.

Sexual Assault Examination

Monique A. Mayo and Christopher J. Russo

INTRODUCTION

Sexual assault is defined as forced sexual contact without consent. Sexual assault involves the threat of force, the use of force, or a person's inability or refusal to give consent (e.g., children, dementia, and unconsciousness).¹ The exact legal definition of sexual assault varies from state to state. Nonconsensual sexual contact involves a continuum ranging from unwanted touching and fondling to forced penetration (i.e., anal, oral, or vaginal). Fingers or objects (e.g., bottles, broomsticks, or knives) could be used instead of or in addition to a penis as a weapon of choice. Drugs (e.g., alcohol, gamma-hydroxybutyric acid [GHB], ketamine, and Rohypnol [flunitrazepam]) are commonly used as "date rape" drugs.²⁻⁴ These agents can be used to disable the victim prior to a sexual assault. **Alcohol remains the most common intoxicant involved in a sexual assault.⁵**

Approximately 300,000 to 700,000 adult women are victims of sexual assault annually in the United States.⁶ The lifetime prevalence of sexual assault for women is 18% to 19% and 2% to 3% for men.^{6,7} The prevalence may be grossly underestimated with only 10% to 15% of all assaults being reported.⁶ Vulnerable populations (e.g., homeless, institutionalized, or sheltered) are not included in most large studies looking at the incidence or prevalence.⁸

Sexual assault is not generally a crime committed by strangers. Most women (78% to 82%) are sexually assaulted by someone known to them.^{6,9} The assailant may be an acquaintance, coworker, family member, neighbor, significant other, or spouse. More than 50% of rape victims over the age of 30 are sexually assaulted by an intimate partner.⁹ Even fewer women report assault when it is committed by someone they know.

Victims do not fit a specific profile. Adolescent girls and young women face particularly high rates of sexual assault.¹⁰ Victims have been reported in all age groups. Sexual assault occurs across all ethnic backgrounds, racial backgrounds, and socioeconomic groups. Up to 39% of women will be raped more than once during their lifetime.⁶

Some victims will not identify themselves as victims of sexual assault.¹ They may be ashamed or fearful to disclose what happened. They may be experiencing the rape trauma syndrome which is a special category of posttraumatic stress disorder. The use of screening questions and a high index of suspicion are necessary to identify these patients. It is clear there is a significant increase in the utilization of medical resources after a sexual assault and early identification of potential victims may be useful.¹¹

The Emergency Department visit of a sexual assault victim is vital in assuring evidence collection and proper medical treatment.^{5,12} Proper follow-up plans, medical appointments, and referrals to local rape crisis centers and/or hotlines are crucial for the mental and physical recovery of victims. The likelihood that the patient will seek follow-up care and pursue the case through legal avenues is strongly influenced by their initial experience in the Emergency Department.¹³ It is critical to not revictimize the patient or make them feel responsible for the sexual assault.¹³

INDICATIONS

Perform a sexual assault examination, including evidence collection, on all patients who present within 5 days of a sexual assault. Evidence collection has the highest yield if collected within 72 hours after the sexual assault. Some states may recommend evidence collection up to 14 days from the alleged sexual assault. Proceed with the examination if the victim is unsure of when the assault occurred or when the patient is unsure if a sexual assault occurred. Perform a thorough history and physical examination with extra attention to the areas violated to evaluate for injuries, even when the patient presents more than 5 days after the sexual assault. Evidence collection requirements vary from state to state. Samples collected prior to the assignment of a case number cannot be admitted as evidence in some states. Be familiar with local laws.

Perform a complete history regardless of when the assault took place.^{1,14} Patients must consent to the evidence collection process (Figure 170-1). Proceed with the evidence collection if a patient is unable to consent due to a medical condition, with local statutes and hospital policy determining the release of evidence. Minors do not require parental consent for the initial evaluation of any potential life-threatening injuries. State laws mandate the age with which a minor can be examined and treated for medical complaints without parental consent related to sexual activity and pregnancy. Many states require parental permission for the release of evidence.

CONTRAINDICATIONS

Manage life-threatening injuries and unstable vital signs according to usual recommendations prior to evidence collection.¹ Sexual assault victims may present with major nongenital physical injuries that must be addressed prior to any assault examination or evidence collection. Up to 5% of sexual assault victims have major nongenital physical injuries.¹⁵ **Do not perform a sexual assault examination if a patient does not consent to the examination unless unconscious or due to a medical condition.** Victims must be able to consent to the examination and evidence collection unless there is a medical reason they cannot consent. Document this reason in the medical record.

EQUIPMENT

- Separate paper bags for clothing and undergarments
- Clean white sheet and/or large paper sheet to place on floor when patient disrobes
- 4 sterile cotton-tipped swabs for oropharynx evidence collection
- Pharyngeal culturettes or nucleic acid amplification test (NAAT) swabs for chlamydia or gonorrhea
- 4 sterile cotton-tipped swabs for vaginal, cervical, or penile evidence collection
- Culturettes or NAAT swabs for vaginal or penile gonorrhea and chlamydia
- Slides for wet mount *Trichomonas* and/or NAAT swabs for vaginal or penile *Trichomonas*

PATIENT CONSENT/AUTHORIZATION TO RELEASE EVIDENCE TO LAW ENFORCEMENT AGENCY

Patient _____

DOB _____ Hospital Patient No. _____

CONSENT

I understand that in addition to consent for medical evaluation and treatment given to the hospital and physician, I also give consent to a medical examination for evidence of sexual assault. I understand that the evidence collected in the State Police Evidence Collection Kit will be sent to the Illinois State Police Forensic Sciences Command for the sole purpose of analysis to determine sexual activity relating to the investigation of sexual assault. I understand that this exam may include reference samples. I also understand that I may withdraw consent at any time for any portion of the exam.

Patient, Parent, Guardian (please circle)

I understand that collection of evidence may include photographing injuries and that these photographs may include the genital area. Knowing this I consent to having photographs taken.

Patient, Parent, Guardian (please circle)**RELEASE**

I hereby authorize _____ to release to _____
(Name of hospital) (City) (Law enforcement agency name)

the following information covering treatment given to me on _____
(Month) (Day) (Year)

AUTHORIZED FOR RELEASE**NOT AUTHORIZED FOR RELEASE**

(check those which apply)

1. Copies of Forensic Laboratory Report Form ☐2. State Police Evidence Collection Kit ☐3. Photographs ☐4. X-rays or copies of x-rays taken in connection with exam ☐5. Clothing ☐

Authorized for release (list clothing or miscellaneous items)

Article

Description

Signature of person authorizing release of information _____

Patient, Parent, Guardian (please circle)**STEP 13****RECEIPT OF INFORMATION**

I certify that I have received the following items (check those which apply):

☐ One sealed evidence collection kit☐ X-rays☐ Photographs☐ Swabs/specimens (if no evidence collection kit is used)☐ Sealed paper clothing bag(s) (if more than one sealed clothing bag, please note)☐ Other _____

Signature of person receiving information and/or articles _____ Date _____ Time _____

Officer ID# and rank _____ Representative of _____

Name of hospital representative who is releasing articles _____

(Printed name)

(Signature)

ILSP501

(White copy to hospital; yellow copy to law enforcement agency)

FIGURE 170-1. Sample form for patient consent and release of information to a law enforcement agency. It includes the receipt of information form to be signed by the law enforcement officer when the evidence is transferred to their care. (Courtesy of the Illinois State Police.)

- 4 sterile cotton-tipped swabs for rectal evidence collection
- Culturettes or NAAT swabs for rectal chlamydia and gonorrhea
- Extra sterile cotton-tipped applicator swabs for stains and bite marks
- Comb and a piece of clean white paper for loose pubic hairs
- Comb and a piece of clean white paper for loose head hairs
- 2 sticks for fingernail scrapings
- Filter paper for blood and/or saliva collection, depending on your state requirement
- Urine collection equipment for chlamydia and gonorrhea testing as an alternative to swabs or culturettes
- Urine or blood collection equipment to test for pregnancy
- Equipment for serum collection to test for hepatitis, human immunodeficiency virus (HIV), and syphilis
- Digital camera or forensic photographer for documentation
- Colposcope, as applicable
- Sterile water to moisten speculum and cotton-tipped swabs
- Change of clothing for the patient
- Separate envelopes to place evidence within for each body site
- Tape to seal all evidence that can be written upon with ink

Most states have prepackaged evidence collection kits with most of the necessary equipment included (**Figure 170-2**). These kits

A

B

FIGURE 170-2. Examples of the sexual assault evidence collection kits. **A.** The kit. **B.** Contents of the kit.

A

B

FIGURE 170-3. Examples of toxicology and drug testing kits. **A.** Urine kit. **B.** Blood kit.

usually do not contain paper bags for the clothes, culturettes, NAAT swabs, blood drawing equipment (i.e., needles, Vacutainers), and blood collection tubes. All these are readily available in any Emergency Department.

Use only paper bags and not plastic bags for the collection. Plastic bags retain moisture and do not breathe. This can promote mold formation and destroy DNA evidence.

A separate kit is available for toxicology and drug testing (**Figure 170-3**). Use these items and not hospital supplies for specimen collection and analysis. Do not use the supplies available in the Emergency Department. Kits can be used for urine or blood.

Use a colposcope if trained in its use. This is a routine part of the sexual assault examination and used by some practitioners. The colposcope provides a magnified view of the area and allows one to distinguish any abnormalities. It consists of a monocular or binocular microscope that takes photographs and/or video (**Figure 170-4**). The colposcope picks up details not seen by the unaided eye (e.g., abrasions, bruising, lacerations, and tears). The application of a dye to the tissues allows abnormalities to be easier visualized through the colposcope. The colposcope enhances the examination by being noninvasive, examining internal and external structures, providing light, providing magnification, measuring accurately, and recording images (i.e., photographs and video).

PATIENT PREPARATION

Address any life-threatening injuries and unstable vital signs before proceeding to the formal sexual assault examination. Do not to cut or rip any clothes to best preserve evidence. Cut or torn clothing for the appropriate care of the patient often supersedes

A

B

FIGURE 170-4. Examples of digital colposcopes. **A.** Seiler 955 (Seiler Instruments Inc., St. Louis, MO). **B.** SW-3306. (Jiangsu Sanwe Medical Technology Inc., Jiangsu Province, China.)

any evidence collection. Make a note of any clothing that is cut or ripped for patient care in the medical record.

Conduct the examination in a quiet and private room.¹ The room should ideally have the facilities to perform a pelvic examination so that the patient does not have to be moved multiple times. Assign a designated nurse and physician who are trained in the sexual assault protocol.^{5,16} Keep the number of providers to a minimum. **Be aware of the multiple emotional manifestations that the patient may experience. Safety and privacy must be ensured.** Notify a community-based or hospital-based advocate upon the patient's arrival to the Emergency Department. Advocates can best define their own role. Allow the patient to decide if the advocate should stay for the examination and evidence collection. Contact the Police in the jurisdiction of the sexual assault and the Department of Children and Family Services (DCFS) according to local laws and patient request. All providers can be subpoenaed to testify in the event of legal action. Alert hospital security to the possibility that the assailant may come to the hospital.

The patient, or their guardian for a minor, must give written consent prior to the examination (Figure 170-1). **Obtaining consent has important legal and psychological implications for the patient. It is important to let the victim guide the process as much as possible to help them restore control of their life. Let the victim know that you are their advocate. The sexual assault victim has the right to refuse the sexual assault examination, any medical treatment, and any interviews by advocates or social workers.** Note in the medical record any portions of the sexual assault examination and treatment that the patient refuses. **Encourage the patient to at least have the examination without the use of the sexual assault kit to provide proper medical treatment. Encourage the patient to allow the collection of evidence with the sexual assault kit if they later change their mind and decide to prosecute the assailant.**

Discourage the patient from changing clothes, defecating, drinking, eating or urinating prior to the examination. This is

to best preserve evidence, especially if the patient is seen in close time proximity to the sexual assault. Perform examinations specific to the affected area earlier to accommodate the patient if they need to drink or void.

EXAMINATION OF FEMALE PATIENTS

Exact details of the examination will vary depending upon state and local evidence collection requirements.⁵ Some states have provisions for Sexual Assault Nurse Examiners (SANEs) who are specially trained to perform the complete sexual assault examination and testify if the case is prosecuted.¹⁷ Other regions have a sexual assault response team (SART) with representatives from law enforcement, forensics, health care, the prosecutor's office, and rape crisis centers.¹⁸ SANE and SART programs increase compliance with recommended medical care, quality of evidence collection, and the likelihood that charges will be filed and successfully prosecuted.⁸

The order of the examination may vary depending upon the patient's needs. The Emergency Department is often the first official system to which the victim reports an assault. **Patients may be reluctant to share their story with personnel if they are met with judgmental attitudes or insensitive treatment.**¹⁹

Collect a urine sample early if there is any possibility of the use of a "date rape" drug. The decision to process the urine for toxicologic analysis can be determined later. The window to detect drugs (e.g., GHB or Rohypnol [flunitrazepam]) can be as little as 8 hours after ingestion.^{2,4} Most toxicology screens will detect prescription drugs and recreational drugs that the patient may have taken. For this reason, some patients may decide not to have their urine tested.

HISTORY

Proceed with the history and physical examination once the patient is in a private room, the patient has consented to the examination, and an advocate is made available. Obtain a complete

Illinois State Police
Division of Forensic Services

STEP 2

FORENSIC LABORATORY REPORT (4 PAGES)

Please print, type or use a patient information stamp.

(patient stamp)

Patient Name		DOB	Age	
Race	Sex	Arrival Date		Arrival Time
Address		City		
County	State	Zip	Phone	
Hospital			ER#	
For Children: Name of Guardian			Relationship	
Person providing history			Relationship to patient	

For children: Avoid multiple interviews. Take time to establish rapport. Avoid leading or yes/no questions. Use direct quotes. Avoid surprise or negative emotions, while still showing concern and support.

- Chief complaint of person providing history to include physical injuries and methods employed by perpetrator, i.e., weapons, restraint, biting, threats.
- Chief complaint in child's words to include physical injuries and methods employed by perpetrator, i.e., weapons, restraint, biting, threats.

3. Date of Assault	Time of Assault	4. Location & geographical surroundings of assault			
--------------------	-----------------	--	--	--	--

5. Name(s), number, & race of assailant(s) if known.

6. Sexual acts described by patient/historian

Acts Described	Yes	No	Attempted	Unsure	Acts Described	Yes	No	Attempted	Unsure	
Penetration of vagina by:					Masturbation:					
penis					of victim by assailant					
finger					of assailant by victim					
foreign object					Did ejaculation occur?					
describe object					inside body orifice					
Penetration of rectum by:					outside body orifice					
penis					If outside body orifice, describe location					
finger					Other sexual acts?					
foreign object					If yes, describe					
describe object					Did assailant use condom?					
Oral copulation of genitals:					Did you bite your assailant?					
of victim by assailant					Were you bitten by your assailant?					
of assailant by victim					Victim was licked/sucked?					
7. Post-assault hygiene/activity					If yes, where					
urinated	Yes	No				Victim licked/sucked assailant?				
defecated	<input type="checkbox"/>	<input type="checkbox"/>				If yes, where				
genital wipe/wash	<input type="checkbox"/>	<input type="checkbox"/>								
bath/shower	<input type="checkbox"/>	<input type="checkbox"/>								
douche	<input type="checkbox"/>	<input type="checkbox"/>								
tampon, sponge, diaphragm removed/inserted (circle)	<input type="checkbox"/>	<input type="checkbox"/>								
oral hygiene/intake/vomit	<input type="checkbox"/>	<input type="checkbox"/>								
changed clothes	<input type="checkbox"/>	<input type="checkbox"/>								

8. Pertinent medical history

- Date of LMP
- Sexual activity within 72 hrs. of assault?
Yes No
- Contraceptive used at time of assault?
- Communicable diseases of risk to lab personnel (e.g., hepatitis, TB, HIV, lice, etc.)

(White copy to hospital; yellow copy in kit)

ILSP502A

FIGURE 170-5. Sample history form. (Courtesy of the Illinois State Police.)

history to guide the medical examination and help with possible legal matters (Figure 170-5). **Avoid judgmental questions that may feed into the victim's feeling of self-blame. Focus on asking the patient open-ended questions.** Inquire about the time and

place of the assault, the race of the assailant(s), their gender, and the number of assailants. Obtain and document a brief description of the assault including whether there was oral penetration, rectal penetration, vaginal penetration, and/or ejaculation. Elicit

any use of foreign objects, force, lubricants, or restraints. **Ask the patient and document what they have done since the assault.** Simple things (e.g., bathing, changing clothes, defecating, douching, urinating, or using a tampon) may change the ability to collect forensic evidence.

The past medical history should emphasize the gynecologic history and include last menstrual period, type of birth control used if any, last consensual intercourse, previous sexually transmitted infections (STI), previous pregnancies, and previous gynecologic surgeries. **The time of the last voluntary intercourse is important as mobile sperm may be found for up to 72 hours in the cervix.** Determine the tetanus immune status and provide immunoglobulin and boosters if needed. Try to determine if “date rape” drugs might have been given, especially if there seems to be a lapse of time.²

PHYSICAL EXAMINATION

The physical examination serves to detect injuries and document them for future legal prosecution. Perform a complete physical examination, even if the patient does not want to pursue legal matters. Although up to 70% of rape victims reported no physical injuries, 4% to 5% sustained serious physical injury and 24% sustained minor physical injuries.^{6,20} **It is important to help patients guide the examination and allow them to stop at any point if they are not ready to proceed. Many patients will need encouragement through the examination.**

Note the patient's general appearance, affect, and emotional status (**Figure 170-6**). Instruct the patient to disrobe over a clean paper and sheet if they are wearing the same clothes they wore prior to the assault. Place all clothes in paper bags, with the underwear in a separate paper bag. Fold the paper sheet, containing any debris, and place it in a collection envelope. Examine the entire body for abrasions, bites, ecchymoses, foreign bodies, lacerations, and scratches. **Closely examine every laceration to ensure it is not a stab wound.** Use a body diagram to document any injuries (**Figure 170-6**). Look for any signs of strangulation and document the negative or positive findings.²¹

Genital trauma after consensual sex is possible. Genital injuries can occur from the sexual assault. Most common injuries occur at the fossa navicularis anterior to the fourchette, hymen, labia minora, and posterior fourchette.²² Commonly injured nongenital areas due to the assault include the breasts, mouth, thighs, throat, and wrist.¹⁹ Oral cavity injuries can include broken teeth and a torn frenulum. Bite marks on the breast and genitalia are common.²² Use an alternative light source (e.g., Wood's lamp) to examine the skin for fluorescent stains that may represent saliva, semen, or urine. Use a digital camera or a forensic photographer to document any abrasions, bites, lacerations, scratches, or any other injuries. Use a measuring tape to show the size of each injury that is photographed. Take close-up pictures of the injury for detail and pictures further away to show the body location of the injury. **Photographs are much more informative than body diagrams.**

Collection of forensic evidence usually precedes the gynecologic examination unless the patient is bleeding, has severe lower abdominal pain, or has pelvic pain. Most states have set evidence collection kits and the elements required will vary. Evidence is most useful up to 3 days after an assault. Collection of evidence can be performed up to a week after an assault as patients may not recall the dates exactly. Most sexual assault kits require fingernail scraping, head hair combing, saliva specimens, and blood type screening. Obtain samples of the patient's saliva. Follow the instructions on the state kit for this collection. Obtain a sample of the patient's blood and again follow the instructions

of the state kit which may include the use of filter paper. Allow any specimen on filter paper to air-dry before placing it in the envelope.

Swab any stain on the patient's body that fluoresces under the Wood's light or an alternative light source.²³ Swab all orifices (i.e., anal, oral, and vaginal) even if not penetrated as the recollection of events may change and a negative examination in a nonpenetrated area helps to validate the patient's story. **Use only sterile water or sterile normal saline to moisten a swab. Allow all specimens to air-dry before placing them in envelopes.** Use a wooden stick to scrape under all the patient's fingernails over a piece of white paper to collect the scrapings.

Collect hair samples from the victim. Pluck two or three hairs from the scalp hair and place them in a labeled envelope. Comb the patient's pubic hair over a white piece of paper. Place the comb, paper, and any hair or debris in a labeled envelope. Pluck two or three hairs from the pubic region and place them in a labeled envelope. The process of plucking hairs can be painful and somewhat insensitive to the patient. **Consider asking the patient to pluck the hairs for the evidence collection.** This may be better tolerated by the victim and allows them to actively participate in the process. Hair samples can be obtained later if the case is prosecuted as the patient's hair samples will not change. **Cutting off pieces of hair is of no value as the roots of the hairs are required for the forensic evidence process.**

Inspect the mouth and perioral structures for any signs of trauma. Carefully inspect the frenulum of the lower lip and tongue for bruising or tears. Examine the tonsils, the tonsillar pillars, and the oropharynx for bruising or lacerations. Document and photograph any injuries. Swab the oral cavity thoroughly and allow the swabs to air-dry. Obtain additional swabs for chlamydia and gonorrhea testing in the hospital laboratory. Prepare a wet mount to look for spermatozoa.

Thoroughly examine the anorectal area for signs of trauma (e.g., abrasions, ecchymoses, and lacerations). Document and photograph any injuries. Swab the rectum and anal canal. Send one swab to the hospital laboratory for chlamydia and gonorrhea testing. Place the remainder of the air-dried swabs in envelopes for evidence collection and testing.

The gynecologic examination is usually the most traumatic aspect of the examination for the patient. It may remind them of the assault. **Explain all procedures in simple terms prior to beginning. Allow the patient to help guide the examination.** Do all the forensic evidence collection at the same time as the gynecologic examination. Examine the external genitalia (**Figure 170-7**).²⁴ Document and photograph any injuries. Examine the hymen as it is one of the most common sites injured.²⁵ Document in writing and photographs its shape and any lesions, notches, or injuries. Up to 8% of patients have vulvar trauma.²⁶ Examine the internal vaginal vault and the cervix. **Only use sterile water to lubricate the speculum. Lubricants interfere with forensic evidence collection.**

Collect baseline chlamydia and gonorrhea swabs at the time of the pelvic examination from pooled vaginal secretions and the endocervical canal. This testing can be done via NAAT testing in the urine. Complete the studies based on the policies and procedures of the individual hospital. Obtain additional swabs in the vagina and of the cervix to test for evidence. Allow these to air-dry before placing them in an envelope. Colposcopy is used to detect and document more subtle injuries of the cervix and vagina (**Figure 170-8**).²⁷ Colposcopy increases the detection of genital trauma from 6% to 53% of victims.²⁸

Toluidine blue can be used to identify small abrasions and lacerations not easily detected by looking. It can increase the chances

COMPLETE EVIDENCE COLLECTION STEPS 3, 4, AND 5

After STEP 5, obtain appropriate medical specimens from the mouth for clinical lab testing. Patient may rinse out his/her mouth after specimens are obtained. (DO NOT INCLUDE MEDICAL SPECIMENS IN KIT.)

GENERAL EXAM

Trauma should be recorded on the diagrams below which may be used in a criminal proceeding. These include: lacerations, scratches, bruises (detail size, shape, color), erythema, bites, patterned injury, burns, fractures and stains/foreign materials on body, swelling, tenderness. Be sure to note even the most minor signs of trauma. In children: include anogenital or behavioral symptoms. Note general appearance.

Note abnormalities in diagram and/or text.

TEXT

GENITAL EXAM

- For children: Take time to establish rapport and proceed slowly. Extent of examination, including physical as well as specimens, must be decided on a case-by-case basis by the attending physician. If the examination would be too physically or emotionally traumatic for the child, then specimens may need to be obtained by gently using a moist swab on the external vaginal and rectal areas, especially with small hymenal openings.
- Note all discharge, stains, and foreign materials. Note any bleeding.
- Draw shape of hymen and anus in diagrams.
- Use sterile, non-bacteriostatic water or saline for lubrication of speculum.
- Record all acute trauma (lacerations, scratches, bruises [detail size, shape and color], erythema, bites, patterned injury, burns, swelling, tenderness) and chronic trauma (scarring, notching, pigmentary changes) on below diagrams.

for detection of abrasions and lacerations in sexual assault victims. Apply the dye with a cotton-tipped applicator to the external genitalia and wipe off the excess. Document and photograph any areas of uptake of the toluidine blue. Use the toluidine blue

on the external genitalia prior to the speculum examination as the speculum can result in small lacerations that result in dye uptake.²⁹ The dye is spermicidal and can interfere with wet mount examinations.

INTERNAL EXAM

- * As noted above, most children require only vaginal introital specimens without speculum or bimanual exams. Please individualize.

<p>Vagina and Cervix</p>  <p>Uterus, Adnexa</p>	<ul style="list-style-type: none"> • Note abnormalities in diagram and/or text.
	<ul style="list-style-type: none"> • Note abnormalities on bimanual exam, if indicated.

COMPLETE EVIDENCE COLLECTION STEP 6

Alter Step 6, obtain appropriate medical specimens from the vagina/cervix or male urethra for clinical lab testing (DO NOT INCLUDE MEDICAL SPECIMENS IN KIT.)

RECTAL EXAM

- Digital or anoscopic exam at discretion of physician.
- Note abnormalities on above diagrams and/or text.

COMPLETE EVIDENCE COLLECTION STEPS 7 - 12

After Step 7, obtain appropriate medical specimens from the rectum for clinical lab testing. (DO NOT INCLUDE MEDICAL SPECIMENS IN KIT.) After Step 11, obtain appropriate blood specimens for clinical lab testing. (DO NOT INCLUDE MEDICAL SPECIMENS IN KIT.)

ILSP502C

(White copy to hospital; yellow copy in kit)

FIGURE 170-7. Sample physical examination form with diagrams for the genital examination. (Courtesy of the Illinois State Police.)

FIGURE 170-8. Colposcopy. (Used with permission from www.superstock.com.)

EXAMINATION OF MALE PATIENTS

Perform a complete urogenital examination in male victims looking for abrasions, bites, and lesions (**Figure 170-7**). Observe the same disrobing, specimens, and precautions in male sexual assault victims. Obtain oral, rectal, and urethral swabs for chlamydia and gonorrhea. Chlamydia and gonorrhea can be detected in urine of males eliminating the need for most urethral swabs.³⁰ Swab the penis and scrotum with separate sterile cotton-tipped applicators.

EXAMINATION OF CHILDREN

The procedure for an adolescent or postpubertal child is similar to that of an adult.²⁴ Children are often referred to pediatric hospitals or specially trained physicians to perform the sexual assault examination.²⁴ **Consent from the parent of a minor or from the minor depending on state law is needed for the examination. Assent from a child is necessary to complete the examination. Defer the sexual assault examination of a child to a specialist if you do not have experience in this area.**^{16,24,25} The anatomy and examination of a child are different from that of an adult.³¹ **Do not restrain an uncooperative or combative child as this can result in significant psychological trauma.** Some children may require an examination under procedural sedation or general anesthesia. This is reserved for those with more significant or internal trauma and performed by a pediatric subspecialty physician.

LABORATORY INVESTIGATIONS

Decisions regarding STI testing should be individualized given the potential for these diagnoses to be accessed later despite limitations in all 50 states on the evidentiary use of prior sexual history. Perform testing based on guidelines created and regularly updated by the Centers for Disease Control and Prevention (CDC).³² Test serum for hepatitis B, HIV, and syphilis.³² These are baseline tests and will be repeated in later follow-up testing. Process the chlamydia and gonorrhea tests at the hospital laboratory. **NAATs are the preferred tests for *Chlamydia trachomatis* and *Neisseria gonorrhoeae* regardless of the site. NAAT vaginal testing is the preferred test for *Trichomonas vaginalis*.** Perform a wet mount for *T. vaginalis* if there is no access to NAAT swabs. Perform toxicology screens at the hospital laboratory only if there is a medically necessary reason for the test (e.g., altered mental status). **Individual states have protocols for urine testing at a crime lab to detect “date rape” drugs.**

CHAIN OF EVIDENCE

The work does not stop after the evidence is collected. Each state has different rules for evidence collection. Verify the proper procedure in your current setting. No one should leave or enter the examination room until all evidence is properly tagged and secured. Seal all paper bags and envelopes with evidence tape. Place your signature across the sealed ends of each bag or envelope and the evidence tape. This will make it easier to determine if they have been opened and tampered with. Clearly label each bag or envelope with the patient's name and hospital identification number, the date of collection, the time of collection, the source of the sample, and the printed and signed name of the nurse or assistant. Secure all the evidence in a locked room or cabinet until it can be turned over to a law enforcement officer. Have the officer sign a form stating the officer's name, badge number, the date and time the evidence was transferred, and the name of the physician or nurse releasing the evidence to the officer (**Figures 170-1 and 170-9, Step 13**). Both individuals must sign this form.

AFTERCARE

Referral to a Social Worker, Psychologist, or Psychiatrist may be necessary, especially if a patient advocate is not available. Treat any injuries in the standard manner. Update the tetanus immune status as necessary. Make a written or electronic summary of the complete history and physical examination findings for the medical record (**Figure 170-9**).¹⁴ Place or upload any photographs taken in the medical record.

Provide all follow-up instructions in writing (**Figure 170-10**). Arrange medical follow-up with a primary care physician in 1 to 2 weeks and again in 2 to 4 months.³³ The follow-up appointment should include an examination for STIs, HIV testing, human papillomavirus immunizations, and hepatitis immunizations.

Give all patients a 24-hour crisis phone number as well as a follow-up in 1 to 2 days with the local rape crisis center if the community has one.³⁴ The Rape, Abuse, and Incest National Network (RAINN) offers a 24-hour hotline (1-800-656-HOPE) as well as a website (www.rainn.org) with helpful information for the patient.

Arrange, with the help of the advocate or Social Worker, a safe place for the patient to stay. This is especially important if the offender is not in custody. Encourage the patient not to stay by themselves. A patient may need to be hospitalized in rare instances for psychiatric issues from the assault or for the patient's safety. Children may need placement at the discretion of DCFS.

PREGNANCY PROPHYLAXIS

The risk of pregnancy after a sexual assault is estimated to be approximately 5% if the patient is of reproductive age.³⁵ The American Academy of Pediatrics (AAP), American College of Emergency Physicians (ACEP), and American Congress of Obstetricians and Gynecologists (ACOG) support the provision of emergency contraception to victims of sexual assault.^{1,3,36} There are two categories of emergency contraceptives: emergency contraceptive pills and the Copper-T380A intrauterine device (IUD). The only contraindication to emergency contraception is pregnancy. **Emergency contraceptive pills will not harm an existing pregnancy. IUD placement may disrupt a pregnancy or increase the risk of a serious infection and septic abortion.** Educate the patient that emergency contraception does not protect against HIV or STI.

Early emergency contraceptive pills consisted of high doses of common oral contraceptive pills (Yuzpe method).³⁷ Emergency contraceptives that contain only the progestin component (e.g., levonorgestrel) are better tolerated and more effective than the

(patient stamp)

Photographs — may be taken for evidentiary purposes with the written consent of the patient or the patient's guardian if the patient is a minor. If the patient is a minor and the parent/guardian is not immediately available, photographs may be taken but shall be released to law enforcement personnel and state's attorneys only with the written consent of the parent/guardian. If consent is refused, all photographs and negatives shall be given, without charge, to the parent/guardian.

COMPLETE EVIDENCE COLLECTION STEP 13**FINAL INSTRUCTIONS**

1. Make sure all information requested on all sample envelopes and bag labels have been filled out completely.
2. Separate all forms (Steps 1, 2, and 14) and follow distribution requirements on the bottom of each form.
3. With the exception of the large sealed and labeled clothing bags, return all other evidence envelopes/bags to the kit box.
4. Initial and affix red evidence tape on box top.
5. Fill out information required on kit box top.
6. Hand the sealed kit and sealed bags to investigating officer.

NOTE: If officer is not present at this time, place sealed kit and sealed bags in secure area, and hold for pickup by investigating officer.

PATIENT DISCHARGE MATERIALS

Patient name	DOB/Age
Hospital name/phone	
Date of examination	ER#
Examining physician	

With your consent, a number of specimens were collected from you to provide evidence in court should your attacker be caught and you decide to prosecute.

Additional tests were conducted as follows: ☐ A blood test for syphilis, ☐ A culture for gonorrhea, ☐ Tests for chlamydia, ☐ Other tests _____, and ☐ A pregnancy test to determine pre-existing pregnancy only, not to determine a possible pregnancy as a result of the assault.

VENEREAL DISEASE TREATMENT

- ☐ You were given an antibiotic to prevent gonorrhea. However, you must return in six weeks following this treatment for another test to be sure you do not have syphilis. Return for this test and possible treatment the week of _____ name of drug _____ dosage _____
- ☐ You were *not* given treatment to prevent gonorrhea or any other venereal disease because _____
- ☐ If you wish to obtain follow-up testing or treatment for venereal disease, please visit your local health clinic or contact _____ (name, address, and telephone)
- ☐ Patient declines

PREGNANCY PREVENTION

- ☐ You were given medication to prevent pregnancy as a result of the sexual assault. If you should become pregnant despite having been given treatment, you should return immediately to the hospital emergency room or go to your private physician because the drug you were given may cause damage to the fetus. Name of drug _____ Dosage _____
- ☐ You were *not* given medication to prevent pregnancy because _____
If you want counseling, referrals and/or follow-up pregnancy testing information, consult the social service department of this hospital or call one of the agencies listed below for assistance.
- | | |
|-----------------|-----------------|
| Agency _____ | Agency _____ |
| Address _____ | Address _____ |
| Telephone _____ | Telephone _____ |
- ☐ Patient declines

FOLLOW-UP

- ☐ An appointment was made for you at this hospital for follow-up *medical* treatment on (date) _____
- ☐ No appointment was made for follow-up medical treatment because _____
- ☐ An appointment was made for you at this hospital for follow-up *counseling* on (date) _____
- ☐ No appointment was made for follow-up counseling because _____

PSYCHOLOGICAL SUPPORT referral to

Was written and verbal information given to patient? ☐ Yes ☐ No

DOCUMENTATION If the patient is less than 18 years of age, was DCFS notified, if appropriate? ☐ Yes ☐ No

Were police notified? ☐ Yes ☐ No Was Patient Consent and Authorization Form completed? ☐ Yes ☐ No

INFORMATION

I have received the following written information:

- ☐ Illinois Department of Public Health brochure, "After Sexual Assault" ☐ Attorney General's Office flyer "Illinois Crime Victims Compensation Act"
- ☐ Patient Medication information sheets listing anticipated effects and side effects of medicines given to me.
- ☐ This patient information sheet _____ Patient Signature _____ Date _____
- ☐ I do not wish to receive this sheet _____ Patient Signature _____ Date _____

(White copy to patient; yellow copy to hospital)

ILSP514

FIGURE 170-10. Sample patient discharge instruction form. (Courtesy of the Illinois State Police.)

Yuzpe method.³⁸ Data have shown that a single 1.5 mg dose of levonorgestrel is equally effective up to 5 days after unprotected intercourse.^{39,40}

The U.S. Food and Drug Administration has approved the emergency contraceptive pill ulipristal acetate (Ella). Studies have shown pregnancy rates 42% lower than with levonorgestrel when used up to 72 hours after unprotected intercourse and 65% lower when used between 72 and 120 hours after unprotected intercourse.^{41,42}

The Copper-T380A IUD (ParaGard) is the most effective form of emergency contraception and can be inserted up to 5 days after unprotected intercourse.⁴³ The copper IUD is 99% effective in reducing the risk of pregnancy and can be used for up to 10 to 12 years. There is no evidence to support the routine use of prophylactic antibiotics prior to the placement of an IUD.⁴⁴

The ACOG believes that emergency contraception should be provided and immediately available where victims of sexual assault are treated.³⁶ Emergency contraception should be available in hospitals and facilities where victims of sexual assault at risk of pregnancy are treated.⁴⁵ There are hospitals that may still prohibit contraception and practitioners who morally object to it. Promptly refer patients to a center or provider where they can receive the appropriate treatment.

ANTIMICROBIAL PROPHYLAXIS

Postexposure prophylaxis for STI is recommended since compliance with follow-up visits remains poor. The risk of acquiring an STI is relatively high and the side effects from the medications are relatively low. The most common infections diagnosed during sexual assault exams are bacterial vaginosis, chlamydia, gonorrhea, and trichomoniasis.⁴⁶ The current CDC recommendation is to provide prophylaxis for chlamydia, gonorrhea, and trichomoniasis. The current CDC treatment regimen consists of 250 mg of intramuscular ceftriaxone, 2 gm of oral metronidazole or oral tinidazole, and 1000 mg of oral azithromycin in one-time single doses.³² The current guidelines do not recommend prophylaxis for syphilis. The side effects of metronidazole/tinidazole include significant nausea that may interfere or complicate pregnancy prophylaxis. Recent alcohol consumption is a contraindication to immediate oral treatment and can be deferred until 24 or 72 hours after the alcohol. Patients can take the treatment at home. **The most updated guidelines for STI treatment can be found at www.cdc.gov or on their application called “STD Tx (treatment)” available as a download.**

Hepatitis B vaccination, without hepatitis B immunoglobulin, is recommended if the patient has not been previously vaccinated.³² This is especially important in high-risk exposures (e.g., unprotected penetration, contact with the assailant's blood, or contact with the assailant's bodily fluid). Provide the first dose of the hepatitis B vaccine in the Emergency Department. Boosters are recommended at 1 to 2 months and 4 to 6 months.

Human papillomavirus vaccine is recommended for female victims from age 9 to 26 years old who have not been previously vaccinated. It is recommended for men from age 9 to 21 years or 9 to 26 years for men who have sex with men.³² Boosters are recommended at 1 to 2 months and at 6 months.

There are no clear guidelines for postexposure prophylaxis (PEP) for HIV.⁴⁷ The guidelines are individualized according to factors increasing the risk of HIV infection. These include the site of penetration (i.e., oral is lowest versus vaginal versus rectal being highest), trauma, and the presence of lesions from other infections or ulcers in the assailant or the victim.⁴⁸ Discuss the possible benefits of PEP with the patient, noting the specific risks and benefits of HIV prophylaxis. Have a specific discussion regarding the importance of adherence, close follow-up, and early initiation.³² Document this

discussion in the medical record. The current recommendations for PEP include a 28-day course of highly active antiretroviral therapy (HAART). **Consult the CDC website at www.cdc.gov/hiv for specific medication regimens.**

Treatment for the male sexual assault victim is the same except for pregnancy prophylaxis.

COMPLICATIONS

There are no physical complications to performing the sexual assault examination. **Be aware of potential psychological complications.¹³ Treat the patient with the utmost privacy and dignity to help them through this stressful situation. Do not further victimize the victim. Do not add to the abuse they have already suffered. Allow the patient to make decisions and have control during the history and physical examination.** The STI medications can cause allergic reactions, disulfiram reactions with alcohol, and gastrointestinal upset.

SUMMARY

The Emergency Department plays a key role in providing quality treatment to the sexual assault victim. Providing compassionate care strongly influences the healing process from being a victim to becoming a survivor. It is important to perform a complete examination for trauma and not just focus on evidence collection. Careful collection and documentation of the elements of the evidence collection kit will impact successful prosecution. Refer to the CDC website for the latest treatment recommendations. Proper follow-up care and a strong link to a local rape crisis center are important.

Culdocentesis

JoAnna Leuck and Jennalee Cizenski

INTRODUCTION

Culdocentesis is a procedure used to sample peritoneal fluid to help confirm a diagnosis or to obtain a culture. It has mainly been used for diagnosing a ruptured ectopic pregnancy or ruptured ovarian cyst.¹⁻¹¹ Culdocentesis involves introducing a hollow needle through the posterior vaginal cuff and into the peritoneal space.¹⁻¹¹ This is a relatively simple and fast procedure. **Ultrasound (US) has virtually replaced culdocentesis as the test of choice.** US is minimally invasive, has high sensitivity, has a high specificity, and involves no ionizing radiation. Culdocentesis may still prove to be an important skill for the Emergency Physician to consider using for unstable patients and in low-resource settings that do not have US capabilities.

ANATOMY AND PATHOPHYSIOLOGY

The key anatomy to be familiar with is the vagina and the posterior cul-de-sac (i.e., the rectouterine pouch or the pouch of Douglas). The posterior cul-de-sac is formed by reflections of the peritoneum between the posterior surface of the uterus and the anterior surface of the rectum (**Figure 171-1**). It is the most dependent intraperitoneal space in both the upright and supine positions. This allows blood, pus, and other free fluids to pool in this space. The posterior cul-de-sac separates the upper portion of the rectum from the uterus and the upper portion of the vagina. The small intestine and a small amount of peritoneal fluid often lie within the posterior cul-de-sac. The sensory innervation of the vagina is greatest near the introitus. There is minimal sensory innervation in the posterior vaginal fornix adjacent to the posterior cul-de-sac.

INDICATIONS

Culdocentesis has been used in the Emergency Department in the past to diagnose a ruptured viscus, particularly an ectopic pregnancy. The use of culdocentesis has decreased significantly with the emergence of improved serum and urine tests for pregnancy, increased accessibility to US, and increased resolution of US. Recent studies have clearly shown US to be more sensitive and noninvasive in detecting a hemoperitoneum.¹

The primary indication for this procedure is a hemodynamically unstable female patient of reproductive age with evidence of peritoneal irritation in the pelvic region when bedside US is not available.

A

B

FIGURE 171-1. Anatomy of the female pelvis. **A.** Midline sagittal view. **B.** View from above inside the pelvis.

This patient most likely has a ruptured ectopic pregnancy and needs emergent surgery. A diagnostic test is usually not necessary to take the patient directly to the Operating Room if a rapid pregnancy test is positive. **An unstable patient cannot be sent to the Radiology Department for an US if there is any diagnostic uncertainty.** A culdocentesis may be performed if bedside US is not available.

Approximately 85% to 90% of patients with ruptured ectopic pregnancies have a positive culdocentesis.²

Culdocentesis could also be considered in a stable pregnant patient with US evidence of free fluid in the pelvis or posterior cul-de-sac. A culdocentesis can confirm if the fluid is blood. Approximately 65% to 70% of patients who have a stable presentation and unruptured ectopic pregnancy have a positive culdocentesis.

A culdocentesis is indicated if US or a laparoscopy is not readily available. A negative culdocentesis may be used to reassure the Emergency Physician that following serial quantitative beta-human chorionic gonadotropin levels can be performed before committing a stable patient to an operative procedure. A positive culdocentesis would indicate intraabdominal bleeding that requires immediate operative intervention.³

Other indications for a culdocentesis include the evaluation of ascites, blunt abdominal trauma, or patients with pelvic inflammatory disease. It can be performed to obtain ascitic fluid to evaluate for infection, malignancy, and/or type of fluid (i.e., an exudate or transudate). Culdocentesis has been used in place of a diagnostic peritoneal lavage (Chapter 84) to detect hemoperitoneum in blunt abdominal trauma because small amounts of blood tend to collect in the posterior cul-de-sac. Aspiration of clear peritoneal fluid makes significant hemoperitoneum very unlikely. US and computed tomography (CT) scanning have significantly reduced the usefulness of culdocentesis for this indication. Intraperitoneal fluid from patients with pelvic inflammatory disease can be cultured to guide treatment, especially in treatment-resistant cases.

CONTRAINDICATIONS

There are a few contraindications to performing a culdocentesis. An US is the preferred diagnostic method to confirm intraperitoneal bleeding if it is available in a timely manner. A pelvic mass detected on bimanual pelvic examination is a contraindication. A pelvic mass may be a tubo-ovarian abscess, an appendiceal abscess, an ovarian mass, or a pelvic kidney. There is a concern of rupturing an abscess into the peritoneal cavity with the culdocentesis needle. Other contraindications include a nonmobile uterus and patients with a coagulopathy. The procedure is limited to patients beyond puberty on the basis of anatomy. It is difficult to perform the procedure through a small prepubertal vagina. **A patient with unstable vital signs and a positive bedside pregnancy test should be immediately taken to the Operating Room and does not require a culdocentesis. They will require fluid and blood resuscitation until the surgical team and Operating Room are available.**

Culdocentesis may be unsatisfactory in women with previous salpingitis and pelvic peritonitis because the posterior cul-de-sac may have been obliterated. **Failure to obtain blood does not exclude the diagnosis of a hemoperitoneum. The lack of blood on culdocentesis cannot exclude an ectopic pregnancy as the false-negative rates can be as high as 15%.^{4,5}**

EQUIPMENT

- Exam table with stirrups
- Water-soluble lubricant
- Vaginal speculum
- Cervical tenaculum
- 19 gauge butterfly needle or 18 gauge spinal needle
- 25 and 27 gauge needles
- Ring forceps
- 20 mL aspirating syringe
- Povidone iodine or chlorhexidine solution

FIGURE 171-2. The sizes of the ER-SPEC. (Photo courtesy of OBP Medical.)

- Sterile water
- Cotton balls
- 4×4 gauze squares
- Local anesthetic solution with epinephrine
- 4% cocaine (optional)
- 20% benzocaine (optional)
- Red top test tube for laboratory analysis
- Purple top test tube for laboratory analysis
- Culture tubes
- Light source

The ER-SPEC is stocked and used in some Emergency Departments (OBP Medical, Lawrence, MA). The single-use speculum is available in three sizes and comes with a built-in light source (**Figure 171-2**). The speculums are available in all three sizes as sterile or nonsterile models. The light source works for 30 minutes and produces no heat. The lack of a cord to the light source or an overhead light is advantageous. No sterilization is needed as with metal speculums which reduces the risk of cross-contamination.

PATIENT PREPARATION

Explain the risks, benefits, potential complications, and alternatives (e.g., US or immediate laparoscopy) to culdocentesis to the patient and/or their representative. Obtain a signed consent for the procedure. Some Emergency Physicians omit the written informed consent for verbal consent. A statement in the chart should state the following: “The risks, benefits, alternatives, and complications were described and discussed in detail. The patient has a clear understanding of these and all questions were answered.” A witness should be noted in the record.

Perform a bimanual pelvic examination to rule out a fixed pelvic mass and to assess the position of the uterus prior to the culdocentesis. Place the patient in the lithotomy position with the head of the table slightly elevated in reverse Trendelenburg position so that the intraperitoneal fluid gravitates into the posterior cul-de-sac. Place the patient's feet in stirrups. Procedural sedation (Chapter 159) or premedication with intravenous narcotics or sedatives is recommended and may make the procedure more tolerable for the patient. Premedication is not required in an unstable patient.

Some Emergency Physicians obtain stat upright plain radiographs in stable patients prior to the procedure. These are performed to assess for a pneumoperitoneum. This will help in determining if

an iatrogenic pneumoperitoneum was secondary to the procedure upon obtaining postprocedural radiographs.

TECHNIQUE

Insert a lubricated speculum as deep into the vagina as possible without causing the patient discomfort. Open the speculum widely so the blades are above and below the cervix. Adjust the light if using an overhead light source. Grasp the posterior lip of the cervix with a toothed tenaculum or ring forceps (**Figure 171-3A**). **Forewarn the patient that grasping of the cervix with a tenaculum may be painful.** Elevate the cervix to lift the uterus and to stabilize the posterior wall of the uterus during the needle puncture. This causes a tightening of the vaginal wall adjacent to the posterior cul-de-sac to expose the puncture site and keeps it from moving away from the needle as the vaginal wall is punctured.

Prepare the area. Swab any secretions out of the vagina. Swab the vaginal wall in the area of the posterior cul-de-sac with povidone iodine or chlorhexidine followed by sterile water. Some Emergency Physicians may optionally choose to topically anesthetize the area with a cotton ball soaked in 4% cocaine or 20% benzocaine prior to infiltrating with local anesthetic solution. Insert the cocaine- or benzocaine-soaked cotton ball into the posterior vaginal fornix area

FIGURE 171-3. Culdocentesis. A speculum has been inserted in the vagina and opened. **A.** Grasp the posterior lip of the cervix with a toothed tenaculum and elevate it. The “X” marks a spot 1 cm (red arrow) from the junction of the cervix and posterior vaginal wall where the needle will be inserted. **B.** The needles used for anesthesia and culdocentesis are inserted. **C.** Midsagittal section demonstrating the needle is inserted and aimed slightly posterior to access the fluid.

and allow it to remain for 3 minutes. The maximum dose of cocaine to apply to the cotton ball is 3 mg/kg.

Arm a 5 mL syringe containing local anesthetic solution with epinephrine with a 25 gauge needle. Insert the needle in the midline and 1.0 cm posterior (i.e., inferior) to the point at which the posterior vaginal wall joins the cervix (**Figure 171-3B**). Inject 2 mL of local anesthetic solution containing epinephrine into the tissues of the vaginal wall.

Fill a 20 mL aspirating syringe with 2 to 3 mL of sterile saline. Local anesthetic solution can be used instead of saline but it is bacteriostatic and any aspirated fluid cannot be cultured. Attach an 18 gauge spinal needle to the 20 mL syringe. Insert the spinal needle parallel to the lower blade of the speculum (**Figure 171-3B**). Penetrate the vaginal wall in the midline and 1.0 cm posterior (i.e., inferior) to the point at which the vaginal wall joins the cervix (**Figures 171-3B and 171-3C**). Advance the needle 2.0 to 2.5 cm.^{4,6} **Slowly inject 0.5 to 1.0 mL of saline.** It should flow freely and without resistance if the needle tip is within the posterior cul-de-sac (**Figure 171-3C**). **It may be within the wall of the uterus or intestines if there is resistance to saline injection.** Withdraw and redirect the tip of the needle until the saline flows freely upon injection. Aspirate any pelvic fluid and remove the needle. Apply negative pressure to the syringe while slowly withdrawing the needle. **It is important to avoid aspirating any blood that has accumulated in the vagina from previous needle punctures or cervical bleeding.**

Fluid may not be aspirated. Withdraw the needle and reintroduce it slightly to the left or right of the midline. Avoid directing the needle too far laterally. This can result in puncture of a mesenteric or pelvic vessel. Always repeat the procedure once if no fluid is obtained on the first attempt.

Place some of the peritoneal fluid into both a red top and purple top test tube. Place some of the fluid into aerobic and anaerobic culture tubes. Observe the fluid for clotting. Transport the samples to the laboratory for Gram stain, culture, cell count, and hematocrit.

ALTERNATIVE TECHNIQUE

Slight alterations in the technique described above have been used successfully. Longitudinal traction on the cervix instead of grasping and elevating the posterior lip of the cervix is sometimes used to elevate the uterus. A 19 gauge butterfly needle held with ring forceps can be used instead of the spinal needle (**Figure 171-4**).

FIGURE 171-4. The alternative technique of using a butterfly needle and a ring forceps to perform a culdocentesis.

This allows for good control of the needle during the puncture and also offers a built-in guide for needle depth. An assistant is required for this alternative technique to aspirate the tubing while the Emergency Physician positions and withdraws the butterfly needle.

ASSESSMENT

A normal culdocentesis when there is no pathology should yield 2 to 4 mL of clear-to-yellowish peritoneal fluid. There is no diagnostic value when there is no return of fluid of any type, also known as a dry tap. The culdocentesis is considered nondiagnostic if less than 2 mL of clotting blood is obtained. This may have come from a puncture site on the vaginal wall.

A hemoperitoneum is signified by the aspiration of more than 2 mL of nonclotting blood. It has been suggested that as little as 0.3 mL of nonclotting blood equates with a positive tap.⁷ The finding of nonclotting blood with a hematocrit greater than 15% has been 70% to 97% predictive of a significant bleeding source (e.g., an ectopic pregnancy).³ Approximately 70% to 83% of ectopic pregnancies will have nonclotting blood on culdocentesis. Approximately 10% to 20% of ectopic pregnancies will have a negative or nondiagnostic culdocentesis. False positives will occur in 2% of cases.⁸

Culdocentesis is less sensitive with unruptured ectopic pregnancies. It is estimated to be 70% positive with an unruptured ectopic pregnancy versus 85% to 90% positive in a ruptured ectopic pregnancy.⁹ A quantity of blood greater than 2 mL has no further significance as it may be related to needle position or rate of bleeding. Blood remains nonclotted for days in the syringe due to defibrination activity of the peritoneum. A ruptured ectopic pregnancy, a hemorrhagic ovarian cyst, or a ruptured spleen can all result in a hemoperitoneum. Peritoneal bleeding usually corresponds to a hematocrit of greater than 10%. One study showed that 97% of cases with an ectopic pregnancy had a hematocrit of at least 15%.¹⁰

A positive culdocentesis with a positive pregnancy test is not always an ectopic pregnancy. A ruptured corpus luteum cyst is the most common cause of a false-positive result. The false-positive rate is estimated at 9%.

A culdocentesis is considered negative when the aspirated fluid is pus, cystic, or straw-colored and performed for the purpose of diagnosing an ectopic pregnancy. Greater than 10 mL of clear fluid most likely indicates a ruptured ovarian cyst, aspiration of an intact corpus luteal cyst, ascites, or possibly carcinoma. **Obtaining greater than 10 mL of clear fluid does not automatically rule out an ectopic pregnancy since it may coexist with other pathology.**²

US was far superior in recent studies comparing US versus culdocentesis.¹ The sensitivity and specificity of echogenic fluid for establishing a hemoperitoneum were 100% and 100%, respectively, for an US compared with 66% and 80%, respectively, for a culdocentesis. The negative predictive value of a nondiagnostic culdocentesis was 25% compared to 100% for echogenic fluid seen on US in the ectopic pregnancy subgroup of patients.

AFTERCARE

Aftercare is limited to local wound care of the puncture site. Proper postsedation monitoring and precautions are necessary. Bleeding from the tenaculum puncture sites on the cervix and/or the vaginal wall needle puncture site is usually self-limited. Apply manual pressure with a gauze square to provide hemostasis. Obtain an upright plain radiograph to rule out an iatrogenic pneumoperitoneum from the procedure. Compare this film to any preprocedural films.

COMPLICATIONS

Complications associated with performing a culdocentesis are rare. The most common and serious complication reported includes the rupture of an unsuspected tubo-ovarian abscess.⁴ Other complications include puncture of the gravid uterus, bowel perforation, perforation of a pelvic kidney, and bleeding from the puncture site in patients with bleeding disorders. Bowel and uterine wall punctures usually do not result in serious morbidity. Most complications are eliminated by a careful bimanual examination to detect a pelvic mass prior to the procedure.

SUMMARY

Culdocentesis can be very useful in evaluating for a ruptured ectopic pregnancy. It is easy to perform, rapid, and relatively safe. Its utility has decreased as the test of choice with the improved capability and availability of US. It is indicated when US is not available or in unstable patients where bedside US is unavailable.

Prolapsed Uterus Reduction

Andrea Dreyfuss and Eric R. Snoey

INTRODUCTION

Symptomatically important uterine prolapse can result from relaxation of pelvic support with age in susceptible women. Uterine prolapse can significantly impact a woman's daily activities, sexual function, ability to exercise, and body image. Population-based studies note that approximately 10% of women report symptoms of pelvic organ prolapse.¹ Approximately 14% of 16,616 participants possessing a uterus were found to have uterine prolapse in the Women's Health Initiative Hormone Replacement Therapy Clinical Trial.² Pelvic organ prolapse was the etiology for 15% to 18% of

hysterectomies.³ The most common etiology in postmenopausal women for a hysterectomy is uterovaginal prolapse.³ Manual reduction of the prolapsed uterus and placement of a pessary represent a safe and temporizing measure that may be performed in the Emergency Department. Surgical correction may ultimately be necessary. It is estimated that pelvic organ prolapse is responsible for more than 200,000 surgical repair procedures each year (22.7 per 10,000 women). This chapter will address the nonsurgical management of a prolapsed uterus.^{2,4-7}

ANATOMY AND PATHOPHYSIOLOGY

The structural support of the female pelvis is subject to a number of identifiable stresses that may predispose certain women to uterine prolapse later in life. Multiparity is the most commonly shared trait, suggesting that birth trauma has a primary role to play. Alternative mechanisms relate to increased intraabdominal pressure (e.g., heavy lifting, ascites, obesity, large intraabdominal tumors, chronic constipation, or pelvic tumors). A congenital form of uterine prolapse seen in newborns has been attributed to vigorous crying.⁸ Two cases of acute uterine prolapse after restrained motor vehicle collisions were described in 1997.⁹ It was hypothesized that the sudden increase in intraabdominal pressure from the lap belt was the cause of the prolapse.⁹ Chronic respiratory disorders (e.g., asthma, bronchitis, or emphysema) may put undue tension on the pelvic floor musculature and contribute to the increased risk of prolapse.¹⁰ The integrity of the pelvic connective tissues may have a role as suggested by the increased incidence of uterine prolapse in women with Marfan syndrome and other connective tissue disorders.¹¹

Uterine prolapse is defined as the descent of the uterus and cervix down the vaginal canal toward the vaginal introitus. All forms of uterine prolapse are described in reference to the hymen. The uterine displacement is typically graded on a scale of 0 to 4, with 0 referring to no prolapse, 1 halfway to the hymen, 2 at the hymen, 3 halfway out of the hymen, and 4 referring to total prolapse (**Figure 172-1**).^{2,12} A first-degree or mild prolapse is defined with the cervix palpable as a firm mass in the lower third of the vagina. Patients with grades 0 or 1 prolapse are usually asymptomatic. Grade 3, or moderate prolapse, is characterized by the cervix being visible and projecting into or through the vaginal introitus. The patient may experience a falling-out sensation or may report the feeling of sitting on a ball.¹² Additional symptoms include heaviness in the pelvis, low backache, lower abdominal discomfort, and inguinal discomfort. Grade 4, also known as severe prolapse or procidentia, involves the cervix and entire uterus projecting through the introitus, completely inverting the vaginal vault (**Figure 172-2**).¹³ The uterine mass frequently has one or more areas of easily bleeding atrophic lesions secondary to exposure and local pressure effects. It may result in leukorrhea, abnormal uterine bleeding, or spontaneous abortions.⁷

The pelvic diaphragm, the endopelvic fascia, and the vagina provide the primary support for the pelvic organs. The superficial muscles of the perineum lie below the pelvic diaphragm and indirectly support the pelvic organs by inserting centrally into the perineal body. The perineal body serves to fix the distal vagina and anus. The bony pelvis is the ultimate support for all the soft tissues of the pelvis.¹¹

The pelvic diaphragm is made up of a bilaterally paired group of striated muscles (i.e., the pubococcygeus and puborectalis, the iliococcygeus, and the coccygeus). The pelvic diaphragm is innervated by fibers originating from sacral segments 4 and 5. The pelvic diaphragm is normally in a state of tonic contraction. It increases its tone reflexively in response to increases in intraabdominal pressure.¹¹

The endopelvic fascia is the layer of fibrous connective tissue that envelops all pelvic organs. The endopelvic fascia develops supportive

FIGURE 172-1. Stages of uterine prolapse. (Used with permission from reference 12.)

thickenings along lines of tension that are referred to as ligaments (i.e., uterosacral and cardinal ligament complex). These ligaments provide further support for the pelvic structures. The uterosacral and cardinal ligaments suspend the uterus and are simple extensions of the endopelvic fascia.¹¹

The vagina has supportive functions. The uterosacral and cardinal ligaments shift the upper one-third of the vagina posteriorly and laterally. This provides support for the cervix. The middle third of the vagina is attached bilaterally to the fascia overlying the pelvic sidewall musculature and supports the bladder. The lower third of the vagina is fused to the tissues about the vaginal outlet.

There are numerous contributing factors in the development of a prolapsed uterus.¹² Prolonged labor can lead to significant pelvic floor damage suggesting that women who delivered vaginally or who later required cesarean section because of failure to progress are more at risk.¹¹ No clinical indicator has been identified as of yet that allows reliable prediction of pelvic floor dysfunction in apparently normal individuals following vaginal delivery.¹¹ The quantity and quality of collagen appear to deteriorate in women after menopause, likely attributable to the resultant estrogen deficiency.^{14,15} It is

thought that defective connective tissue contributes significantly to uterine prolapse in the absence of other risk factors. One study of premenopausal women with uterine prolapse found a 25% reduction in the collagen content of tissues.¹⁵ Conditions that affect spinal cord pathways and pelvic nerve roots (e.g., muscular dystrophy, trauma, myelodysplasia, meningocele) can result in paralysis of the pelvic floor with the subsequent prolapse of pelvic structures. Spina bifida has been associated with the majority of cases of uterine prolapse in newborn girls and nulliparous women.¹¹

Increased intraabdominal pressure is a major factor in the development of pelvic organ prolapse. Obesity contributes to pelvic prolapse by increasing intraabdominal pressure that is transmitted to the pelvic organs. Chronic respiratory conditions that are associated with forceful coughing are also thought to predispose women to uterine prolapse. Occupational and recreational activities (e.g., heavy lifting or repeated jumping) result in repeated and prolonged increases in intraabdominal pressure. A review of 1.6 million women found an increased risk of uterine prolapse in a group of nurses whose jobs required heavy lifting.¹¹ The deterioration in muscle function and connective tissue associated with aging together with gravity, childbirth, neurologic deterioration, and hormonal status all combine to lead to a progressive decline in pelvic floor function. This may be compounded by factors that increase intraabdominal pressure leading to the development of symptomatic pelvic floor prolapse.¹⁴

All aspects of the vaginal support should be carefully surveyed when examining a patient with a uterine prolapse. Look for the presence of a cystocele or rectocele. Examine the patient in the standing position and the dorsal lithotomy position. The prolapse is almost invariably worse when the patient is upright.¹⁴ It may be necessary to have the patient strain to assess the full extent of the prolapse.¹⁵ The examination may be facilitated by having the patient stand with one foot on a well-supported stool. Some degree of a cystocele, urethrocele, enterocele, or rectocele may develop or may be associated with a uterine prolapse as the uterus progressively descends. Some authors recommend expanding the traditional speculum examination by using a single blade speculum (e.g., Sims speculum) or a bivalve speculum to selectively visualize each portion of the vaginal vault for defects in pelvic support. Perform a rectovaginal examination with the patient in the standing position to detect an occult enterocele suggested by the presence of small bowel easily palpable in the cul-de-sac using the thumb and forefinger.^{16,17}

FIGURE 172-2. Uterine procidentia. (From Cunningham GF et al: *Williams Obstetrics*, 23rd ed. New York: McGraw-Hill; 2010. Used with permission from Dr. Charles P. Read.)

Asymptomatic uterine prolapse requires no treatment in the Emergency Department.¹² The patient with only intermittent symptoms can prevent against prolapse by simply inserting a tampon or a diaphragm. This additional support may be used in anticipation of increased activity or prolonged periods of standing. Inform the patient that she is losing some aspects of pelvic support and should be referred to a Gynecologist for evaluation of future treatment options.⁸ Lifestyle changes can prevent the progression or recurrence of prolapse and preclude the need for future surgical evaluation and complications. Most of these changes focus on limiting unnecessary increases in intraabdominal pressure (e.g., losing weight, removing girdles, avoiding heavy lifting, stopping smoking, treating allergies, and treating pulmonary disease).⁵ Kegel proposed a series of pelvic muscle exercises for the treatment of urinary incontinence that can accompany uterine prolapse. These exercises strengthen the pelvic muscles and may be helpful early. Kegel exercises were associated with improvement of symptoms in a meta-analysis including over 2300 women with uterine prolapse. They are of limited value in patients with significant prolapse since fascial attachments have already been disrupted.^{8,18,19}

Symptomatic women can be treated conservatively or surgically.¹² Pelvic organ prolapse is frequently not recognized until advanced disease is present. Prolapse does not become symptomatic until the descending segment is at or through the introitus.²⁰ Therapeutic options are variable and relate to the age and health of the patient, the severity of the symptoms, and the degree of prolapse. The options for uterine prolapse include observation, reduction with or without supportive pessary therapy, vaginal hysterectomy with corrective therapy for pelvic relaxation (i.e., hysteropexy), and some form of colpocleisis (i.e., surgical obliteration of the vagina).²¹

INDICATIONS

Conservative management of symptomatic uterine prolapse in the Emergency Department involves reduction and subsequent fitting of the patient with a pessary. The pessary is largely used as an alternative to surgery or as a temporizing measure in patients awaiting surgery.²² Preoperative use of a pessary in advanced degrees of prolapse may aid in decongesting the mucosa, improving circulation, and reestablishing vaginal tonicity. Patients desiring surgical management may be treated conservatively in the Emergency Department and referred to a Gynecologist. Symptomatic women who wish to complete childbearing before having a surgical repair may be candidates for a vaginal pessary.⁵ The gynecologic and obstetric indications for pessary support after reduction of the prolapsed uterus are listed in **Table 172-1**.¹⁰

TABLE 172-1 The Indications for the Placement of a Pessary ¹⁰
Gynecologic Indications
Aid in the healing of cervical stasis ulceration associated with uterine prolapse
Nonsurgical management of uterine prolapse
Reduction of a cystocele, enterocele, or rectocele
To alleviate the complications of free uterine retroposition and adnexal prolapse
To control stress urinary incontinence
To determine if future hysteropexy will relieve backache associated with uterine malposition
To facilitate hysteropexy by holding the uterus in position for operation
To reduce infertility due to cervical retroposition
Obstetric Indications
To avoid threatened abortion due to uterine retroposition and chronic passive congestion
To prevent postpartum subinvolution or retroversion of the uterus
To prevent and protect against abortion in cervical incompetence
To relieve urinary retention and/or pain that can accompany uterine retroposition in pregnancy

CONTRAINDICATIONS

There are no absolute contraindications to the manual reduction of a prolapsed uterus. Pessaries are contraindicated in patients with acute genital tract infections and in those with adherent retroposition of the uterus.¹⁰ Any vaginal inflammation, ulceration, infection, or atrophy should be treated before pessary fitting to decrease the likelihood of vaginal erosions and granulation tissue formation. These latter conditions can be mitigated by oral or topical estrogen supplementation. The use of large amounts of lubricants (e.g., K-Y Jelly) should be encouraged with the pessary in the event that estrogen is contraindicated.²² Other contraindications include impaired mental capacity, lack of patient dexterity, a history of non-compliance, severe atrophic mucosal changes, exposed foreign body (e.g., mesh), or sexually active women unable to remove and reinsert the pessary.

EQUIPMENT

- Pessaries (**Figures 172-3 and 172-4**)
- Standard pelvic bed
- Vaginal speculum
- Water-soluble lubricant
- Culture swabs
- Biopsy and Pap smear brush, optional
- Uterine forceps
- Sterile gloves

FIGURE 172-4. The use of different types of pessaries. (Photo courtesy of Cooper Surgical, Inc., Trumbull, CT.)

The vaginal pessary is of ancient lineage. They are now made of plastic, rubber, or silicone. The silicone variety has the advantage of being flexible and pliable while causing less vaginal discharge and odor than rubber.²¹ Pessaries are available in numerous sizes and shapes (**Figures 172-3 and 172-4**). A well-placed pessary supports prolapsing structures against the perineal body and pubic bone (e.g., the uterus, cervical stump, or hernias of the pelvic floor).¹⁰ The pessary is inserted into the vagina to reduce prolapsed tissue inside the vagina, provide support to pelvic structures, and relieve pressure on

adjacent structures (e.g., the bladder and bowel).²³ They elevate the vagina and maintain normal anatomic relations thereby reducing vaginal relaxation and increasing the tautness of the pelvic floor structures. Usually all that is needed is adequate support anteriorly and a reasonably good perineal body. Otherwise, the pessary may slip from behind the pubic symphysis and extrude from the vagina.¹⁰ Patients who are sexually active are unable to remove certain pessaries (e.g., Gellhorn and the donut). The education of Emergency Physicians is somewhat compromised in the use of pessaries.

Placement of a pessary is often a trial and error experience. Review the accompanying pessary brochures to obtain the most satisfactory results from the pessary.²¹

PATIENT PREPARATION

Explain the risks, benefits, and alternative procedures to the patient and/or their representative. Obtain an informed consent for the procedure and place this in the medical record. Place the patient in the lithotomy position with both feet comfortably resting in stirrups. An assistant should be available to assist with positioning.

TECHNIQUES

The management of complete uterine prolapse in the Emergency Department depends upon successful replacement of the uterine fundus into the pelvis and subsequent fitting of the appropriate pessary. Refer the patient for surgical management upon discharge from the Emergency Department. An incarcerated uterus in the pregnant patient is an obstetrical emergency requiring immediate surgical elevation. Other obstetric emergencies include any pregnant patient who develops acute urinary retention or is at risk of aborting.¹⁰

UTERINE REDUCTION

Insert one gloved and lubricated hand into the vagina with the fingers extended to identify the margins of the cervix. Allow the uterine corpus to rest in the palm of the hand. Apply firm and gentle pressure to elevate the uterine fundus with the gloved hand by pressing against the cervix. Use the fingers on the edges of the uterus closest to the cervix to gently manipulate the uterus in the direction of the umbilicus. Gradually replace the uterus into the pelvis.

If this maneuver is not successful, insert a pessary into the posterior vaginal fornix while the patient is in the lithotomy position. Instruct the patient to sit up and assume the knee-chest position after insertion of the pessary. Instruct the patient to slip slowly into the prone position and then into the lithotomy position. The pessary will maintain the uterus in anteposition.

It may be necessary to pack the vagina following manual reduction of a procidentia to maintain the uterine position as a preoperative management decision of an ulcerated or infected prolapse.^{10,24} This should be performed in consultation with a Gynecologist.

FITTING OF THE PESSARY

Measure the distance from the introitus to the posterior vaginal vault using uterine forceps after reduction of the uterus. This measurement minus 1 cm is the approximate length of the pessary. If an ovoid rather than a round pessary is required, place the forceps into the introitus to about the level of the cervix and separate the handles until the blades touch the walls of the vagina. This represents the greatest diameter or approximate width of the pessary.¹⁰

Liberal lubricate the pessary. Insert it with its widest dimension in the oblique diameter of the vagina to avoid painful distension of the introitus. Use the fingers of the nondominant hand to support the perineum. Slip the posterior bar behind the cervix using a finger on the dominant hand. The forefinger should pass easily between the sides of the frame and the vaginal wall at any point to ensure adequate fitting. The pessary is too large if this is not possible.¹⁰

ASSESSMENT

Ask the patient initially to walk around the examination room to confirm comfort and to exclude renewed prolapse or any expulsion of the pessary. Replace the pessary with one of a different size or style to prevent any further prolapse.

AFTERCARE

Instruct the patient to remove the pessary each night and clean it with warm soapy water during the first few weeks of use. The soap should not contain any deodorants, detergents, or perfumes. These agents can irritate the vaginal mucosa and result in a chemical vaginitis. Weekly cleanings and overnight removal are adequate after the patient has become comfortable with its use. Apply vaginal cream once a week if the patient is not receiving systemic supplemental estrogen replacement. Warm, low-pressure acetic acid douches or acidic vaginal creams (e.g., Aci-Jel) may relieve irritation and prevent any discharge caused by the vaginal pessary.¹⁰

Refer the patient to a Gynecologist 1 to 2 weeks after the procedure. Routine follow-up at 1 to 2 months and every 12 months thereafter is recommended after several weeks of a well-managed and appropriately sized pessary. Additional care of these devices includes biannual pelvic examinations and replacement of pessaries every 12 to 18 months.⁵ Instruct patients on the hazards of leaving the pessary in for prolonged periods of time and the importance of complying with recommended follow-up. It is not uncommon to have to change the pessary size and/or type. Patients are sometimes unable to manage the responsibilities of a pessary. A family member or a nurse trained in the insertion, removal, and care of the pessary is an appropriate alternative.

Advise all patients to return to the Emergency Department for difficulty urinating or defecating, signs of infection, or any problems with insertion and removal of the pessary.

COMPLICATIONS

Attempts at reducing the symptomatic uterine prolapse may be unsuccessful. Review the surgical and medical options with the patient and arrange the appropriate follow-up. Consult a Gynecologist before the patient is discharged from the Emergency Department.

A loose pessary is ineffective and usually will be expelled. The patient may experience symptoms if the pessary is too large or not removed and cleaned periodically (e.g., pelvic pain, vaginal bleeding, vaginal ulcers, urinary retention, urinary fistulas, bowel fistulas, vaginal discharge, and/or dyspareunia). Proper initial fitting and appropriate follow-up are important to mitigate these issues.²¹

Minor complications include ulceration and abrasions of the vaginal mucosa secondary to local pressure effects. Pessaries act as foreign bodies and if colonized by bacteria can lead to a vaginitis. Many patients experience a physiologic watery discharge with pessary use. This should not be confused with an infectious process that usually is accompanied by itching, burning, or odor. Severe vaginitis is more common in the elderly and debilitated patients because of the inability to remove and cleanse the pessary.^{25,26} Treat these conditions with discontinuation of the pessary until the infection has cleared and local care with estrogen or antibiotic creams.²²

Serious complications are a result of prolonged (e.g., often decades) uninterrupted use and neglect rather than directly a result of the pessary itself.²² Case reports described in the literature include vesicovaginal fistulas, rectovaginal fistulas, urosepsis, and malignancy.²⁷ Cervical and vaginal cancer is a rare complication and may be related to prolonged irritation or the chemical constituents found in older pessary models.²⁷ Pessary-related infections can occasionally develop local complications (e.g., abscess, sinus tract, pelvic cellulitis) or spread to other systems and cause systemic manifestations (e.g., pyelonephritis or peritonitis). Patient counseling and adequate follow-up are important.²² All of the complications are preventable and point to the need for periodic gynecologic examinations in pessary users.²⁵

SUMMARY

Reduction of the prolapsed uterus with subsequent pessary placement is a safe and acceptable mechanism for management of women who present to the Emergency Department with symptomatic prolapse. Emergency Physicians should be familiar with this technique and recognize women who are most at risk in order to avoid related complications.

Urethral Catheterization

Richard Dean Robinson and Caleb Andrew Rees

INTRODUCTION

The first recorded bladder catheterization was by Oribasius of Pergamon (325–403 AD) in a description of a fistula surgery. Philip Syng Physick tied Chief Justice Marshall to the bed and introduced instruments through a bladder catheter to break up bladder stones. August Mercer developed the coudé catheter in 1863. The bend near the tip, known as an elbow in French, made passage in a stenosed urethra easier. The current Foley catheter was developed in the 1930s by Urologist Frederick Foley. There have been no major changes in the Foley catheter in over 90 years.

Urethral catheterization is the most frequent retrograde manipulation of the urinary tract. It is routinely performed for diagnostic and therapeutic reasons in both urologic and nonurologic diseases.^{1–11} Catheters may be inserted as an in-and-out procedure for immediate drainage, left in place with a self-retaining device for short-term drainage, or left indwelling for long-term drainage.^{6,7} **Although this is one of the more routinely performed procedures in the Emergency Department, great care must be taken to avoid lower urinary tract injury, reduce the introduction of infection, and minimize patient discomfort.** The basic principles underlying urethral catheterization are gender neutral.^{6,7} **It is important to respect the patient's need for modesty and privacy as much as possible.**

ANATOMY AND PATHOPHYSIOLOGY

The genitourinary system is frequently divided into upper and lower urinary tracts. The former refers to the kidneys and ureters, or those structures above the bony pelvis. The lower urinary tract includes the bladder and urethra, or those structures contained within or below the bony pelvis. Although the entire urinary tract may be catheterized, it is the lower tract, namely the urethra, that will be the focus of this chapter.

Averaging 4 cm in length, the female urethra is rarely a focus of difficulty. Most of the confusion related to urethral catheterization in the female results from poor anatomic knowledge of the external genitalia (**Figure 173-1**). The clitoris is often mistaken for the urethral meatus. This can result in catheter-related trauma, bleeding, patient discomfort, and frustration on the part of the patient and the person inserting the catheter. After lateral retraction of the labia minora and exposure of the vaginal vault, the cephalad-most structure is the clitoris. Traveling in a caudal direction, the orifices encountered are the urethra, the vagina, and then the anus.

The male urethra is most often the site of catheter-associated difficulty.³ The male urethra may extend upward of 20 cm in length and follows a tortuous course. The male urethra is named based on the anatomic structure with which it traverses or travels. The distal-most portion of the male urethra is the meatus, followed proximally by the penile, bulbar, membranous, and prostatic portions

(**Figure 173-2**). Resistance to the advancement of a catheter may occur at any point along the course of the urethra as a result of meatal stenosis, urethral strictures, urethral valves, false urethral passages, an enlarged prostate, inflammatory processes, malignant processes, bladder neck constrictions, urethral disruptions, and/or bladder neck disruptions. A careful clinical history and thorough physical examination will, in most cases, uncover these causes. The two most common sites that may be difficult for the catheter to pass are the junction between the bulbar and membranous urethra and the bladder neck.

INDICATIONS

Urinary catheterization can be performed for diagnostic and/or therapeutic reasons.^{2,5,12,13} Urethral catheterization is often performed in females to collect urine for culture and avoid contamination from skin and vaginal flora. This is usually not necessary in males. Measurement of residual (i.e., postvoid) urine, urinary output monitoring in critically ill patients, treatment of urinary incontinence, and facilitation of postsurgical healing are all indications for urethral catheterization. It can be performed to facilitate diagnostic studies such as retrograde cystography and urodynamic evaluations. The main therapeutic indication for urethral catheterization is to relieve acute or chronic urinary retention (**Figure 173-3**).^{14–18} Patients with neurogenic bladders are often taught self-catheterization so they may perform this procedure at home. Other indications include bladder irrigation, extensive burn wounds, instillation of medications into the bladder, intraoperative monitoring of urine output, perineal pressure sores with incontinence, prolonged immobilization (e.g., lower extremity fractures, multiple traumatic injuries, pelvic fractures, unstable spine injury), surgery of the urinary tract or nearby structures, the intubated patient, and to improve end-of-life care.

FIGURE 173-1. External anatomy of the female genitourinary tract.

FIGURE 173-2. Anatomy of the male genitourinary tract.

CONTRAINDICATIONS

The only absolute contraindication to urethral catheterization is in patients with known or suspected traumatic injury to the lower urinary tract.^{2,4,5,19} They should not undergo urethral catheterization until urethral continuity has been confirmed radiographically. Physical signs on examination that might suggest urethral trauma include blood at the urethral meatus, a perineal hematoma, or a high-riding prostate. **Attempts at urethral catheterization may convert a partial urethral disruption into a complete disruption.** Refer to Chapter 176 for the complete details regarding retrograde urethrography and cystography.

There are a few relative contraindications to urethral catheterization. Microscopic or gross hematuria in the absence of lower urinary tract trauma is not a contraindication to urethral catheterization. Patients with grossly bloody urine are at risk for urinary retention secondary to obstructing clots and require urethral catheterization for bladder

FIGURE 173-3. Sagittal view of the enlarged bladder on an abdominal computed tomography scan.

irrigation and continuous drainage. Although hypocoagulable states are not contraindications to urethral catheterization, great care must be exercised to avoid iatrogenic trauma and uncontrollable bleeding of the urethra. Prior placement of a penile prosthesis or an artificial urinary sphincter is not a contraindication to catheterization. However, vigorous attempts at inserting the catheter are discouraged. Urethral catheterization should not be performed in an uncooperative or combative patient unless they are sedated and/or restrained. A Urologist should be consulted prior to urethral catheterization in patients with known urethral strictures or recent surgery of the urethra or bladder neck. Children who have a screening urine analysis can use a bag or one of the other techniques to noninvasively obtain urine.²⁰⁻²⁴

The Choosing Wisely Campaign recently published results. Each specialty chose tests or procedures that were not necessary, low yield, or caused more harm than benefit. Emergency Medicine chose, among others, to avoid using bladder catheters routinely in stable patients to decrease the number of catheter-associated urinary tract infections.¹⁹ This included catheterization of the bladder for convenience of the patient, convenience of the staff, morbid obesity, patient refusal, patients with dementia, patients with delirium, patients who are intoxicated, and urine output monitoring when the patient can use a urinal.

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- Sterile gloves
- Commercially available kit containing the components listed below
- Water-soluble lubrication gel
- Lidocaine jelly in penile applicator (i.e., Uro-jet)
- Sterile drapes
- Urethral catheters (Foley, coude, filiform, and followers)
- Christmas tree adapter
- Pediatric feeding tubes, sizes 5 to 8 French
- Sterile saline
- 10 mL syringe
- Urine meter, if catheter is to be retained
- Urine collection system
- Urethral catheter leg strap, if catheter is to be retained
- 1 inch tape
- Benzoin solution
- Ultrasound (optional)
- Ultrasound gel (optional)
- Ultrasound transducer cover (optional)
- High-frequency linear array or micro-convex transducer (optional)

Foley catheters are the most commonly placed urethral catheters. A Foley catheter is a dual lumen tube that contains an inflatable cuff near the distal end (**Figures 173-4 and 173-5**). The distal end has two holes for urine to enter the catheter. Urine traverses the large inner lumen of the catheter to exit the proximal port. The second lumen is extremely small and allows air or fluid to flow into the inflatable cuff. The proximal end contains two ports. One port allows egress of urine from the catheter. The second port is an inflation port. An air-filled or saline-filled syringe attaches to this port and is used to inflate the cuff. When inflated, the cuff prevents the distal end of the catheter from slipping out of the bladder.

Foley catheters come in a variety of sizes and styles. A 14 or 16 French catheter is the size most commonly used in adolescent or

FIGURE 173-4. The schematic of a urethral catheter. (Used from www.commons.wikimedia.org/wiki/File:Foley_catheter_inflated_and_deflated_EN.svg.)

adult patients. The two-way catheter is most commonly used. It is designed for urinary drainage. Three-way catheters are employed when bladder irrigation, in addition to urinary drainage, is required. These catheters have a small lumen to inflate the cuff, an intermediate-sized lumen to instill irrigation solution, and a large lumen to drain urine from the bladder. In the Emergency Department, they are placed in patients with gross hematuria and the passage of blood clots that may have caused acute urinary retention.

There are many advantages to the use of bedside ultrasound. It is quick, uses no radiation, shows if the bladder is enlarged, and obviates the need for additional routine workup of abdominal pain until the distended bladder is drained and symptoms are not relieved. Bladder ultrasound increases the successful catheterization procedure.^{24,25} Bedside ultrasound is more accurate than dedicated bladder ultrasound devices.²⁶

PATIENT PREPARATION

Explain the procedure, its risks, and benefits to the patient and/or their representative. **Urethral catheterization must be performed using strict sterile technique.** All equipment needed to perform the procedure should be assembled at the bedside prior to beginning the procedure. The preparation for a male patient will be described below. The preparation for a female patient will be described in the techniques section.

Place the male patient in a bed or gurney. In uncircumcised patients, the foreskin must be retracted to expose the glans penis and the urethra. If a phimosis is encountered, it should be approached accordingly. In the pediatric population, male infants and children often have a physiologic phimosis. **Attempts at aggressive foreskin retraction should be avoided.** Clean any dirt and debris from the penis. Apply povidone iodine or chlorhexidine solution, with cotton balls or swabs and allow it to dry. Place sterile drapes around the penis to isolate a sterile field.

Generous lubrication and anesthesia of the male urethra is one of the most important aspects of urethral catheterization.^{9,10,27-30} A water-soluble lubricant (e.g., K-Y Jelly) or local anesthetic lubricant (e.g., 2% lidocaine jelly) can be applied to the tip of the urethral catheter before it is inserted. Unfortunately, this provides little to no anesthesia. Ideally, commercially packaged blunt-tip syringes of lidocaine jelly (e.g., the Uro-jet, Amphastar Pharmaceuticals Inc., Rancho Cucamonga, CA) should be used. Insert the blunt tip of the syringe into the urethral meatus. Firmly squeeze the glans penis to form a seal around the syringe tip. Inject the anesthetic jelly into the urethra. Maintain the syringe tip in the urethral meatus and manual pressure on the glans penis for 10 seconds to prevent egress of the anesthetic jelly. Allow several minutes for the lidocaine jelly to anesthetize the urethra.

Prophylactic antibiotic coverage is generally not indicated for urethral catheter placement. Patients with penile prostheses, artificial urinary sphincters, prosthetic heart valves, vascular grafts, and other indwelling foreign bodies may benefit from prophylactic antibiotics. An intravenous dose of a cephalosporin, quinolone, or other

FIGURE 173-5. Commonly used urethral catheters. **A.** Illustration of the Foley catheter (left) and the coude catheter (right). **B.** Photograph of the distal ends of the Foley catheter (left) and the coude catheter (right).

antibiotic that covers skin and perineal flora may be administered just prior to inserting the urethral catheter in these patients.

MALE CATHETERIZATION TECHNIQUES

FOLEY CATHETER INSERTION

Clean and prep the penis, anesthetize the urethra, and set up a sterile field as mentioned previously. Select an appropriately sized Foley catheter. Inflate the cuff to check its integrity. Deflate the cuff.

Grasp the penis with the nondominant hand. Pull the penis taut and upright to straighten out the penile urethra (**Figure 173-6A**). Retract the foreskin if the patient is uncircumcised. **Do not forget to reduce the foreskin after inserting the catheter to prevent the formation of an iatrogenic paraphimosis.** Grasp the Foley catheter with the dominant hand. Dip the tip of the catheter in, or an assistant can apply, water-soluble lubricant or anesthetic jelly. Insert the catheter into the penile urethra via the meatus (**Figure 173-6A**). Gentle and continuous pressure helps open the urogenital sphincter to let the Foley catheter pass. Continue to gently but firmly advance the Foley

FIGURE 173-6. Foley catheter insertion. **A.** The lubricated catheter is inserted into the urethra. **B.** The catheter is advanced until the ports are at the meatus. **C.** Cross-section of the male pelvis showing the distal catheter positioned within the bladder. **D.** Urine aspiration confirms proper placement of the catheter. **E.** The cuff at the tip of the catheter is inflated. **F.** The catheter is gently withdrawn to lodge the cuff against the bladder neck.

catheter into the urethra until the proximal ports are at the urethral meatus (**Figure 173-6B**). This ensures that the distal tip of the catheter and the cuff will reside within the bladder (**Figure 173-6C**). If the distal end of the catheter is not completely within the bladder, inflation of the cuff inside the urethra will result in severe pain, hematuria, and possible urethral rupture.

Urine should begin to spontaneously flow out of the large port. Insert the proximal end of the catheter into a sterile container to collect urine. If urine does not spontaneously flow out of the large port, attach a 60 mL syringe to the port and aspirate urine to confirm proper placement of the catheter (**Figure 173-6D**). Consider using transabdominal ultrasonography to confirm proper catheter placement and the presence of urine within the bladder. Deflate the cuff if no urine is aspirated and/or ultrasound imaging does not confirm appropriate placement. Remove the catheter from the urethra and reattempt the procedure.

Attach an air-filled or saline-filled syringe to the cuff inflation port (**Figure 173-6E**). Inject air or saline to inflate the cuff (**Figure 173-6E**). Inject only the volume of air or sterile saline recommended by the catheter manufacturer. This can be found on the catheter package and is often printed on the cuff inflation port. Remove the syringe from the cuff inflation port. Gently withdraw the Foley catheter until resistance is met. This signifies that the cuff is lodged against the bladder neck (**Figure 173-6F**). Attach an adapter and urine collection system to the urine port of the Foley catheter. Reduce the previously retracted foreskin, if present and retracted, once the catheter placement is confirmed.

Secure the catheter. Wrap tape around the urine port of the catheter and continue it onto the adapter and first 3 to 5 cm of the collection tubing. This will prevent the system from disconnecting. Tape the collection tubing to the patient's thigh to prevent it from pulling out the adapter or the catheter when the patient moves. Some authors also secure the catheter as it exits the penile urethra (**Figure 173-7**).⁵ This is especially important if a red rubber catheter or uncuffed coude catheter is used as these cuffless catheters

FIGURE 173-7. A method to secure the urethral catheter as it exits the penis.⁵

are not self-retaining. Place three thin strips of tape along the length of the penis and attach them to the catheter. Benzoin solution can be applied to the penis to aid in adhesion of the tape. Place a piece of tape circumferentially around the tape ends attached to the catheter to secure the tape strips. **Never apply tape circumferentially around the penis as it may cause ischemia.**

DIFFICULT URETHRAL CATHETERIZATION

Difficulty is commonly encountered when inserting a urethral catheter. Urethral pathology (e.g., valves, strictures, or folds) or prostate enlargement can often be overcome by switching from a Foley to a coude catheter and the application of digital assistance. If unsuccessful, filiforms and followers can often be employed to successfully insert the catheter. Foreskin edema from anasarca, pelvic lymphatic blockage, a paraphimosis, or penile trauma can often cover the glans penis and urethral meatus. Attempt to reduce the edema manually or with an elastic bandage (Chapter 179). Significant edema may require penile anesthesia and needle decompression (Chapters 177 and 179) or a dorsal slit of the foreskin (Chapter 181). A phimosis may be physiologic or acquired in children and the result of scarring in adults from repeated bouts of inflammation, infection, or sexually transmitted diseases. A phimosis may require a dorsal slit of the foreskin (Chapter 181) to allow for urethral catheterization or a dilation of the phimotic opening.

The DirectVision™ microendoscope (PercuVision LLC, Columbus, OH) consists of a rolling cart, fiberoptic endoscopic bundle, and tri-lumen silicone catheter. The cart houses a color monitor and the fiberoptic light source (**Figure 173-8A**). A disposable fiberoptic bundle is attached to the light source and is inserted through the tri-lumen catheter (**Figures 173-8B and 173-8C**). The fiberoptic bundle transmits light to the tip of the catheter and images back to the monitor. The system allows visually guided urethral catheterization in the male patient. It may decrease urinary tract trauma during catheterization, improve catheterization success rates, and simplify the catheterization process. The major limitation of this product for routine urethral catheterization is due to the initial expense of the system and the cost of the single-use disposable endoscopic bundles and catheters. This device may be commonly used in the future as costs decrease and clinical information becomes more readily available.

COUDÉ CATHETER INSERTION

The coude catheter is similar to a Foley catheter except that the distal end is curved and the tip has a small rounded ball (**Figure 173-5**). The catheter was designed to bypass the areas of the urethra that a straight catheter could not negotiate. A coude catheter may be used if a Foley catheter cannot be passed into the bladder. It may also be used if the patient has a known urethral stricture, urethral valve, narrow urethra, or enlarged prostate.

The coude catheter comes in various sizes and styles. Some models contain a cuff while others do not. The catheter is inserted into the urethra with the elbow on the tip of the catheter facing anteriorly. The procedure for placement of the catheter into the bladder is the same as that for a Foley catheter.

DIGITAL ASSISTANCE

Occasionally, the Foley or coude catheter tip will become caught in a posterior fold of the urethra just distal to the urogenital diaphragm (**Figure 173-9A**).³¹ Place the fingers of the nondominant hand on the perineum between the scrotum and anus (**Figure 173-9B**). Apply upward pressure on the perineum to direct the catheter tip upward while simultaneously advancing the catheter with the

FIGURE 173-8. The PercuVision DirectVision microendoscope. **A.** The cart. **B.** The catheter with the light source inserted. **C.** The proximal catheter. (Photos courtesy of PercuVision.)

dominant hand through the urogenital diaphragm and into the bladder. An assistant is often required to hold and stabilize the penis while the Emergency Physician uses their hands to manipulate the catheter and perineum.

If the patient has an enlarged prostate, the bladder neck is often elevated superiorly and anteriorly. Digital assistance on the skin of the perineum may be unsuccessful. A finger in the rectum may be used to move the catheter tip anteriorly so that it can be advanced into the bladder.

FILIFORM AND FOLLOWER CATHETERS

In patients with severe urethral strictures or urethral folds, it may be impossible to pass a Foley catheter or a coude catheter. The next step in the progression to catheterize the bladder is to use filiform and follower catheters. Filiforms are very narrow, flexible, and solid catheters. Their sole function is to successfully negotiate a strictured urethral segment and enter the bladder. The distal end of the filiform catheter may be straight or pig-tailed and is available in a variety of sizes (**Figure 173-10A**). The proximal end of the filiform

catheter is a standard size and contains a metal female connector (**Figure 173-10B**). The followers are flexible, hollow catheters that attach to the filiform catheters. The distal end of the follower catheter contains a metal male connector that attaches to the proximal end of the filiform catheter and a hole to allow urine to enter the catheter (**Figure 173-10C**). Follower catheters come in a variety of sizes and allow the Emergency Physician to dilate the urethra and catheterize the bladder. The proximal end of the follower catheter is open and accepts a Christmas tree adaptor (**Figure 173-10D**).

A filiform and follower should be used only after unsuccessful catheterization attempts with a Foley catheter and/or coude catheter. Do not use them if there is contrast extravasation on a retrograde urethrogram, a urethral disruption (real or potential), or urethral trauma. The patient has already been prepped and draped for the prior catheterization attempts. Re-instill anesthetic jelly into the urethra to ensure adequate anesthesia. Numerous sizes and shapes of filiform and follower catheters should be available at the bedside. An assistant will be required to open each sterile packet and hand the filiforms and followers to the Emergency Physician as needed.

FIGURE 173-9. Digital assistance. **A.** The Foley catheter is caught in a posterior urethral fold. **B.** Digital upward pressure on the perineum will direct the catheter tip upward and through the urogenital diaphragm.

FIGURE 173-10. Photographs of the ends of the filiform and follower catheters. **A.** Distal ends of the filiform catheter. **B.** Proximal ends of the filiform catheter. **C.** Distal ends of the follower catheter. **D.** Proximal ends of the follower catheter.

FIGURE 173-11. Insertion of the filiform catheters. **A.** The catheter is inserted and advanced into the urethra (straight arrow) with a twisting motion (curved arrows). **B.** Additional catheters are inserted until one advances into the bladder. The numbers represent the order of insertion of the filiform catheters.

Grasp the cleaned, prepped, and anesthetized penis with the nondominant hand. Pull the penis taut and upright to straighten out the penile urethra (**Figure 173-11A**). Grasp a filiform catheter and dip the tip in water-soluble lubricant or anesthetic jelly. Gently insert and advance the filiform catheter into the urethra with a twisting motion (**Figure 173-11A**). Stop advancing the filiform catheter when resistance is met (**Figure 173-12A**). Insert a second well-lubricated filiform catheter into the urethra with a twisting motion until it meets resistance (**Figure 173-12B**). Gently attempt to advance the first filiform catheter. If it will not advance, insert a third filiform catheter (**Figure 173-12C**). Continue to insert filiform catheters and gently manipulate the previously inserted filiform catheters (**Figure 173-11B**). Continue this process until one filiform catheter advances into the bladder so that its proximal end is 2 cm from the tip of the penis (**Figure 173-12C**). Remove all the filiform catheters except the one that entered the bladder (**Figure 173-12D**).

Choose a follower catheter to insert into the bladder. Liberally lubricate the tip of the follower catheter and attach it to the filiform catheter (**Figure 173-13A**). Gently advance the follower catheter until its proximal end is 3 to 4 cm from the tip of the penis (**Figure 173-13B**). **If the follower catheter meets resistance during its advancement, do not force it into the urethra.** Instead, withdraw the follower catheter until the tip is 2 to 3 cm outside the penis. Remove the follower catheter from the filiform catheter. Attach a 1 or 2 French smaller well-lubricated follower catheter onto the filiform catheter and attempt to advance it into the bladder. Continue this process until a follower catheter can be completely advanced into the bladder. The filiform catheter will be completely curled up inside the bladder (**Figure 173-13B**).

Urine should flow spontaneously from the properly positioned follower catheter. If not, attach a 60 mL syringe and Christmas tree adaptor to the follower catheter (**Figure 173-13C**). Apply negative pressure to the syringe to aspirate urine and confirm the proper

FIGURE 173-12. Midsagittal section of the penis demonstrating insertion of the filiform catheter. **A.** The filiform catheter is inserted until resistance is encountered. **B.** A second filiform catheter is inserted until it encounters resistance. **C.** A third filiform catheter is inserted and advances into the bladder. **D.** Filiform catheters #1 and #2 have been removed.

FIGURE 173-13. Insertion of the follower catheter. The filiform catheter has been previously inserted into the bladder. **A.** The follower catheter is screwed into the filiform catheter. **B.** The follower catheter is advanced into the bladder. **C.** Urine aspiration confirms proper placement.

placement of the tip of the follower catheter. Attach a urinary collection system to the follower catheter and secure the catheter as described previously. Inadequate local anesthesia may require procedural sedation and anesthesia (Chapter 159) or general anesthesia.

The use of filiforms and followers has many complications. The creation of a false passage, urethral injury, and urethral perforation are possibilities. Bleeding can be the result of any of the latter. The use of multiple instruments increases the risk of infection.

The patient with urinary obstruction cannot be discharged home with a filiform and follower catheter inserted inside the bladder. If the follower catheter is a size 16 or 18 French, completely withdraw it and the filiform catheter and insert a 16 French Foley catheter. If the follower catheter is smaller than size 16 French, the urethra must be dilated. Withdraw the follower catheter until the

distal tip is 2 to 3 cm outside the penis. Remove the follower catheter from the filiform catheter. Attach a 1 to 2 French larger well-lubricated follower catheter onto the filiform catheter and gently advance it into the bladder. Continue this process until a follower catheter that is size 16 French easily passes into the bladder. Remove the filiform and follower catheters. Insert a size 16 French Foley catheter. Secure the catheter as described previously.

FEMALE CATHETERIZATION TECHNIQUES

Place the female patient supine in an examination bed. Place the patient in the frog-legged position. If an examination table equipped with stirrups is available, the patient can be placed in the lithotomy position. Separate the labia with the nondominant thumb and index

FIGURE 173-14. Female urethral catheterization. **A.** External view of the genitalia. The catheter is inserted into the urethral meatus and advanced. **B.** Midsagittal section of the female pelvis demonstrating catheter insertion.

finger to expose the vulva (**Figure 173-14A**). Identify the urethral meatus. Apply povidone iodine or chlorhexidine solution to the urethral meatus and surrounding vulva. Without moving the non-dominant hand, apply sterile drapes to isolate the vulva. A lesser amount of anesthetic jelly is needed to lubricate the female urethra. Place anesthetic jelly on a sterile cotton-tipped applicator. Insert the cotton-tipped applicator just into the tip of the urethral meatus for 8 to 10 seconds. Remove and discard the cotton-tipped applicator. This method of anesthesia is painful and avoided by most.

Grasp the Foley catheter with the dominant hand. Dip the tip of the catheter in, or an assistant can apply, water-soluble lubricant or anesthetic jelly. The use of anesthetic jelly on the catheter provides no anesthesia.^{32,33} Insert the catheter into the urethral meatus (**Figures 173-14A and 173-14B**). Advance the catheter 6 to 8 cm to ensure the distal end and cuff are within the bladder. Urine should flow spontaneously out of the large port. Insert the proximal end of the catheter into a sterile container to collect urine. If urine does not flow spontaneously from the large port, attach a 60 mL syringe to the port and aspirate urine to confirm proper placement of the catheter. The remainder of the procedure is exactly the same as previously described for the male patient.

Some women may present with a cystocele, cystourethrocele, or urethrocele. These abnormalities result in the urethra running posteriorly and inferiorly making urethral catheterization difficult. Insert your gloved and lubricated index and middle fingers into the vagina and gently push superiorly and anteriorly on the anterior vaginal wall. This maneuver will reposition the bladder and urethra to its normal position. Insert the urethral catheter in the usual manner while maintaining anteriorly directed pressure on the anterior vaginal wall.

INFANT AND CHILDREN CATHETERIZATION TECHNIQUES

The indications and contraindications for catheterization of infants and children are the same as for adults. The anatomy of the prepubertal child is similar to the adult except for the difference in size and lack of secondary sexual characteristics. Identifying the urethral meatus can be difficult in uncircumcised boys. An assistant is often required to help position children during the procedure. Gently manipulate and retract the foreskin just enough to expose the meatus. It is worth noting that the urethral orifice may be difficult to identify in a young female due to abundant hymenal tissue covering the vaginal introitus. **This can be circumvented by gentle lateral traction of the labia and downward pressure on the vaginal introital fold with a cotton-tipped applicator which will reveal the urethral opening immediately anterior to the vaginal orifice.** The catheterization of newborns and infants is accomplished with an appropriately sized pediatric feeding tube, usually size 5 French in the neonate up to 8 French in newborns and infants. Small Foley catheters or feeding tubes (e.g., size 10 or 12 French) may be used in children aged 1 to 6 years. Children over 12 years of age can accommodate a 14 French catheter. **The same techniques and cautions followed in the adult patient also apply to the pediatric patient. Advancing the catheter a few centimeters longer than the length of the penis in boys and just a few centimeters in girls is a reasonable approach.³⁴ Children may be more prone to attempting to try and remove the catheter. Ensuring the catheter is adequately secured after placement is paramount.**

REMOVAL OF THE CATHETER

Consider if a urethral catheter is really needed. If so, remove it as soon as possible. Removal is much easier than insertion and does not require anesthesia. Apply gloves. To be safe, also use a mask, eye protection, and a gown. Drain the bladder. Deflate the catheter cuff with a

syringe. Loosely hold the gauze around the catheter near where it exits the body. Pull out the catheter through the gauze to prevent splashing urine. Culturing the catheter tip is on an individual patient basis.

ASSESSMENT

Urine drainage is the sign of appropriate catheter placement. Lubricating gel may plug the outflow port of the catheter. If no urine is seen, apply gentle pressure to the suprapubic area to force the flow of urine. Should this maneuver fail to initiate urine flow, irrigate the catheter with a small volume of sterile saline. The catheter will flush and withdraw fluid with ease if properly positioned in the urinary bladder. Use of an irrigation tray, which includes a 60 mL piston tipped syringe, is recommended. It may require greater than one fill (i.e., more than 60 mL of saline) to produce two-way flow. The inability to successfully irrigate denotes obstruction or misplacement of the catheter. Ensure that the catheter is inserted completely to the hub in males to prevent inadvertent inflation of the cuff in the membranous or prostatic urethra.

AFTERCARE

Always remember to reduce the foreskin after catheter placement to avoid the complication of a paraphimosis in uncircumcised males. Indwelling catheters should be secured to a closed gravity drainage system and attached to the anterior medial thigh. For long-term requirements in males, the catheter should be secured to the anterior abdominal wall to decrease the likelihood of stricture formation.

The patient may be discharged from the Emergency Department with a Foley catheter or coude catheter. Instruct the patient on the proper care and emptying of the leg bag (**Table 173-1**). The patient should immediately return to the Emergency Department if they develop a fever, pain, hematuria, inability to void through the catheter, or abdominal pain. Consider prescribing a 3 day supply of broad-spectrum antibiotics if the patient has valvular heart disease, mitral valve prolapse, cardiac valve replacements, a penile prosthesis, or an artificial joint.

COMPLICATIONS

GENERAL COMPLICATIONS

Creation of false passages, urethral perforations, bleeding, infection, and catheter misplacement are complications associated with urethral catheterization. Urethritis is fairly common following catheterization, especially in patients with urethral strictures or prostatic enlargement. Epididymitis, cystitis, and pyelonephritis are uncommon complications and often seen with prolonged catheterization. Bacteremia can occur following the procedure. High-risk patients should receive antibiotic prophylaxis prior to catheterization.

TABLE 173-1 Patient Instructions for the Proper Care of a Urinary Drainage Bag at Home

1. Always thoroughly wash your hands with soap and warm water before putting on gloves and emptying the drainage bag.
2. Never place the drainage bag on the floor to prevent contamination.
3. Always keep the drainage bag below the level of the genitals to prevent backflow of urine.
4. Clean the drainage port with an alcohol swab before emptying the bag.
5. Always empty the drainage bag into a clean container.
6. Do not touch the drainage port or allow it to touch the container.
7. Close the drainage port after emptying the bag and wipe it with an alcohol swab.
8. Discard the urine in the container and thoroughly wash the container with hot soapy water.
9. Discard the gloves and do not reuse them.
10. Always thoroughly wash your hands with soap and warm water after taking off your gloves.

Urinary tract infection (UTI) is also a common complication after urethral catheterization. It is especially common with a prolonged duration of an indwelling catheter which can lead to susceptibility to a variety of organisms including those that produce biofilms that can adhere to the catheter and external balloon. A recent Cochrane review evaluated the difference between urethral and suprapubic catheterization.³⁵ It found that suprapubic catheters reduced the risk of re-catheterization, pain, and asymptomatic bacteriuria. There was incomplete evidence to comment on whether either method was superior with regard to symptomatic UTI. The evidence was also inconclusive for symptomatic UTI when comparing indwelling and intermittent urethral catheterization. A silver-coated or antibiotic-coated catheter may decrease microbial colonization of the catheter.³⁶

Iatrogenic trauma to the urethra can lead to strictures, hemorrhage, hematuria, or fistulas.^{37,38} Creation of a false passage can occur by inserting the catheter alongside the urethra. Attempts at catheterization in a trauma patient with a urethral injury can convert a partial urethral tear to a complete tear. Failure to reduce the foreskin after catheter placement may result in a paraphimosis.

LEAKAGE AROUND THE CATHETER

Urine may occasionally leak out between the catheter and the walls of the urethra. Make sure that an appropriately size catheter has been inserted. Check the balloon to make sure it is properly inflated. Gently pull on the catheter to seat the balloon at the neck of the bladder. Too large of a catheter or balloon can irritate the urinary tract or bladder and result in bladder spasm and urine leakage. Check the catheter, tubing, and drainage bag for kinks. An occlusion distal to the catheter can result in retained urine, an overdistended bladder, and bladder spasm. Evaluate a urine sample for the presence of an infection. A UTI can result in bladder spasm.

DIFFICULTY REMOVING A CATHETER

A less common complication is difficulty removing an indwelling urethral catheter that has an inflated cuff. Ensure that the catheter is not clamped or kinked. This can compress the cuff inflation lumen. A vacuum may have formed in the inflation lumen causing it to collapse. Attach a syringe without the plunger to the inflation port and release the vacuum followed by aspiration to deflate the balloon. The use of a syringe without the plunger will sometimes deflate the cuff without aspirating. Gently turn the catheter clockwise and counter-clockwise as the catheter may be compressed, kinked, or twisted. Gently advance the catheter further into the bladder and attempt to deflate the balloon. Gently inject 2 to 3 mL of sterile saline through the inflation port to open the inflation lumen or unclog it. Inspection of the valve sometimes reveals the problem. One may attempt to cut proximal to the valve in hopes of evacuating the cuff contents but this is not always successful. **Do not do this unless other methods have failed.**

In patients with a Foley catheter balloon that will not deflate, real-time ultrasound (US) can facilitate percutaneous balloon puncture and removal of the catheter.³⁹ Prepare the skin and apply sterile US gel to the patient's skin. Apply a sterile US transducer cover over the transducer. Stand to the side of the patient so that your dominant hand is cephalad (Figure 174-6). Position the US monitor on the opposite side of the patient so that it is easy to see (Figure 174-7). A longitudinal-oriented US transducer is preferred for the dynamic approach since it allows visualization of the entire needle as it courses toward the bladder. Place the US transducer marker to your left. This will ensure that the left-right orientation on the US screen matches the real-world orientation.

Place the longitudinally oriented US transducer in the suprapubic area and move it from side to side to locate the largest

FIGURE 173-15. Longitudinal US view of the transabdominal spinal needle (arrow) approaching the Foley balloon.

bladder dimension. To deflate a Foley catheter balloon, make sure there is sufficient fluid in the bladder. If necessary, fill the bladder with enough sterile saline through the Foley catheter to make the bladder easily visible on the US monitor. Clamp the Foley catheter to retain the saline within the bladder. Instruct an assistant to apply gentle traction to the external portion of the Foley catheter to fix the balloon against the bladder neck.

Place a 5 inch, 22 or 24 gauge spinal needle on a 10 mL syringe. Position the spinal needle on the cephalad side of the US probe and angle it caudally (Figure 174-6). Insert and slowly advance the spinal needle. Look for the needle on the US screen as it is inserted and advanced. If the needle is a narrow gauge and the US transducer is low frequency, the spinal needle will not necessarily be visible in the tissue. Rather, look for movements in the tissue as the spinal needle is advanced (Figure 174-11). Adjust the needle and the US transducer side to side as needed to keep the needle in the same plane as the US beam. Continue to advance the spinal needle into the bladder (Figures 173-15 and 174-7). Continue to advance the spinal needle toward and into the inflated balloon. Puncture the balloon with the spinal needle. The balloon will deflate with a dramatic “pop.” Remove the spinal needle. Remove the Foley catheter. Inspect the balloon to make sure there are no obvious missing fragments that are retained in the bladder.

Other options include transperineal cuff puncture, blind transabdominal cuff puncture, or injection of an organic agent (e.g., ether, acetone, mineral oil, or toluene) through the inflation port to dissolve the cuff. Occasionally, a narrow gauge guidewire may be placed through the cut balloon port to loosen any concretions that may have formed and allow the cuff to deflate. Obtain a plain radiograph of the pelvis to determine if the catheter is knotted within the bladder.^{40,41} This will require cystoscopic manipulation to unknot the catheter. These techniques to reduce the cuff should be performed in consultation with a Urologist.

INTERMITTENT SELF-CATHETERIZATION

Some patients use self-catheterization at home to empty their bladder. The PerfIC Cath (Adapta Medical, Colorado Springs, CO) is better than the red rubber catheter or reusable catheters. It was designed for patients with limited dexterity including patients with diabetes, multiple sclerosis, spina bifida, spinal cord injury, and stroke. It can also be used by patients with neurogenic bladders,

prostate disorders, or normal dexterity. It is in easy-to-open packaging. The closed system was designed to reduce the risk of infection. Regardless of the system used for intermittent self-catheterization, make sure the patient does it correctly (Table 173-1).

SUMMARY

Although urethral catheterization is one of the most routinely performed urologic procedures, it is not a benign process and should be attempted with mindfulness. A working knowledge of genital and perineal anatomy along with a thorough clinical history and physical examination is paramount to successful catheter placement and avoidance of complications. Liberal amounts of lubrication and topical local anesthetic should always be used when inserting the catheter. Patients requiring chronic indwelling catheters should be versed in catheter care and have routine medical evaluations for catheter change and follow-up.

Suprapubic Bladder Aspiration

Richard Dean Robinson, Teresa Proietti, and Andrew Shedd

INTRODUCTION

Suprapubic bladder aspiration is the insertion of a needle through the anterior abdominal wall and into the bladder to obtain a urine specimen. It is performed to either temporarily relieve urinary retention when the bladder outlet is obstructed and one is unable to place a transurethral catheter or to obtain a sterile urine sample for urinalysis.¹⁻¹⁰ It is most commonly performed in children under the age of 2 years as part of the septic work-up.⁷ The procedure is quick,

simple to perform, safe, and has a low rate of complications. The main advantage of suprapubic bladder aspiration is that it bypasses the urethra and minimizes the risk of obtaining a contaminated urine specimen.

Urinary sampling remains the cornerstone for the diagnosis of many disease processes. Suprapubic bladder aspiration is a viable option, both therapeutically and diagnostically, when the usual means of urine collection or bladder drainage is not possible or preferable. The technique can yield an uncontaminated urine sample without urethral or skin flora contamination.

ANATOMY AND PATHOPHYSIOLOGY

The urinary bladder of the neonate and infant begins as an abdominal organ (**Figure 174-1A**). As the child grows, the pelvis enlarges and the bladder migrates down into the bony pelvis. The bladder eventually assumes a retropubic position that is maintained throughout life (**Figure 174-1B**).

The anatomic knowledge required to perform this procedure is minimal. The pubic symphysis is in the midline and forms the anterior border of the bony pelvis. The bladder resides posterior and superior to the pubic symphysis in the young child. The needle will pass through the skin and subcutaneous tissue of the lower abdominal wall, the rectus sheath, the peritoneum, and the bladder wall.

The adult urinary bladder resides behind the pubic symphysis and has both retroperitoneal and intraperitoneal attachments (**Figure 174-1B**). A working knowledge of this anatomy makes percutaneous bladder manipulation both safe and possible. The rectum lies just inferior and posterior to the urinary bladder. The bladder is attached to the anterior abdominal wall by the urachus which is a fibrous chord.¹¹ The posterior surface of the bladder is lined with the parietal peritoneum.¹¹ The bladder dome has peritoneal attachments and access in this area carries the potential for bowel injury and intraperitoneal bladder perforation. These relationships must be kept in mind when attempting percutaneous access of the bladder.

Multiple major vascular structures, including the common iliac and hypogastric vessels, reside in the bony pelvis alongside the bladder. These structures are lateral to the bladder and eccentric (i.e., off the midline) percutaneous access may result in iatrogenic injury and hemorrhage.

INDICATIONS

Suprapubic bladder aspiration is the preferred method of urinary sampling and drainage in instances where voided specimens are undesirable or unattainable and when urethral catheterization is not technically possible or is contraindicated.^{1-9,12,13} It offers a means of obtaining an uncontaminated urine sample from the bladder. Obtaining a urine sample by urethral catheterization in the neonate or young child may be technically difficult in which case suprapubic aspiration is an alternative. Although urethral catheterization may be an easier method of urine collection in the child or adult, suprapubic aspiration may be required to isolate intravesicular infections, to rule out contamination with asymptomatic bacteriuria, or in cases of urinary retention from a phimosis. The procedure may also be performed to temporarily relieve acute urinary retention of a nonphimotic etiology.

CONTRAINDICATIONS

The single most important aspect of suprapubic bladder manipulation is the presence of an identifiable and distended urinary bladder. The bladder can be identified by palpation, percussion, transillumination, and ultrasonography. Under no circumstances should “blind” percutaneous access be attempted if the bladder is not palpable or visualized with the aid of ultrasonography.

Patients with a coagulopathy are at an increased risk for significant hemorrhage from any percutaneous procedure including suprapubic bladder aspiration. Any coagulopathy, bleeding diathesis, platelet dysfunction, and/or thrombocytopenia should be corrected prior to performing this procedure.

Other contraindications to bladder aspiration exist. The peritoneal cavity has been violated and the bowel may be displaced more caudally and to the level of the urinary bladder in individuals with prior lower abdominal surgery or traumatic injury. The bowel may be adhered to the anterior abdominal wall. This heightens the risk of inadvertent entry into the peritoneal cavity and bowel injury. It should not be performed in patients with bladder cancer or subcutaneous vascular grafts in the suprapubic region. The return of ascitic fluid may lead the Emergency Physician to a false sense of security when the catheter is actually intraperitoneal. Urine leakage in patients with a urinary tract infection may result in bacteremia, peritonitis, and/or sepsis. An uncooperative patient will require

FIGURE 174-1. Position of the bladder. **A.** The bladder is an abdominal organ in the neonate and infant. **B.** The bladder is a pelvic organ in the older child, adolescent, and adult.

parenteral sedation or procedural sedation (Chapter 159) prior to performing this procedure. Any extremity contractures, physical alterations, spinal deformities, truncal obesity, or other conditions that would preclude the patient from lying supine and inhibiting bladder palpation are also relative contraindications to performing a percutaneous cystostomy.

Skin infections of the abdominal wall overlying the puncture site are a contraindication to bladder aspiration. Abnormalities in genitourinary anatomy or enlargement of pelvic structures (e.g., ovarian cysts or uterine fibroids) increase the chance of complications with bladder aspiration. Known neoplastic processes of the lower genitourinary tract heighten the possibility of complications. Distention or enlargement of the abdominal viscera can increase complication rates. The use of ultrasound (US) guidance may decrease associated risks in these situations. US directly visualizes the needle tip in the bladder.

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- Sterile gloves
- 22 to 24 gauge needle or spinal needle, 1½ to 3 inches long for neonates, infants, and young children
- 22 to 24 gauge needle or spinal needle, 3 inches long for older children, adolescents, and adults
- 10 mL syringe
- Injectable local anesthetic solution, most commonly 1% lidocaine
- 4×4 gauze squares
- 25 gauge needle and 3 mL syringe for anesthetic administration
- Sterile towels or drapes
- Specimen containers for urine analysis and culture
- Bandage
- US machine (recommended)
- Sterile US gel
- Sterile US transducer covers
- 5 to 10 MHz linear US transducer for neonates, infants, and children
- 2 to 5 MHz curvilinear abdominal US transducer for adolescents and adults

PATIENT PREPARATION

Explain the risks, benefits, and alternative procedures to the patient and/or their representative. Obtain an informed consent for the procedure and place this in the medical record. When performing the procedure on a neonate or child, it is advisable to give the parent the option to leave the room or look away as the procedure can be disconcerting to some parents.

It is important to identify the distended bladder by palpation, percussion, transillumination, or ultrasonography. Transillumination of the full bladder may be conducted in the neonate. Place the patient supine (**Figure 174-2**). Ultrasonography should be used even when the bladder is readily palpable. US can identify the bladder, quantify the amount of urine in the bladder, guide needle placement, and increase the success of the procedure.¹³⁻¹⁶ If the bladder is distended, it appears on US as an anechoic (i.e., black) rectangular or triangular structure just below the abdominal musculature depending on the transducer orientation.⁶ Identify and mark the skin location immediately above the bladder where it is closest to the skin.

FIGURE 174-2. The frog-leg position. **A.** The infant. **B.** The older child.

Prepare and drape the abdomen in a sterile fashion from the umbilicus to the pubis. Clean the skin of any dirt and debris. Apply povidone iodine or chlorhexidine solution and allow it to dry. Apply sterile drapes. Prepare the US by placing the sterile US transducer cover on the selected transducer. Inject a local anesthetic agent, usually 1% lidocaine, to create a subcutaneous wheal in the area of the intended skin puncture site. Prior teaching was that infants did not need local anesthesia. Recent research has found suprapubic bladder aspiration to be a painful procedure for neonates.^{11,17}

TECHNIQUES

NEONATES & INFANTS

Have an assistant place and hold the neonate or infant supine in the frog-leg position (**Figure 174-2A**). Identify the needle insertion site in the midline and 2 cm cephalad to the pubic symphysis (**Figure 174-3**). The use of US is recommended to assist in determining the proper needle insertion site. Inject 1 mL of local anesthetic solution subcutaneously and into the abdominal wall musculature at the needle insertion site.

Place a 22 or 24 gauge spinal needle onto a 10 mL syringe. Occlude the urethra to prevent reflexive micturition by applying manual

FIGURE 174-3. Anatomic landmarks for suprapubic bladder aspiration in the neonate and infant. A line is drawn from the umbilicus to the pubic symphysis (dotted line). The intersection of the line with the suprapubic crease is the landmark for insertion of the needle.

pressure to the urethral meatus of the female (**Figure 174-4A**) or the glans penis of the male (**Figure 174-4B**). Insert the needle through the anesthetized skin and at a 70° angle from the skin (**Figure 174-4**). Advance the needle cephalad while applying negative pressure to the syringe. Stop advancing the needle when urine is aspirated. On US, the bladder will appear to tent as the needle pierces its anterior wall.⁶ If no urine is aspirated, withdraw the needle to the subcutaneous tissue and redirect it to an 80° angle from the skin. If the procedure is unsuccessful on the second attempt, delay further attempts

until the bladder is more distended, consult a Urologist, or obtain urine through another method.¹⁸⁻²² After urine is obtained, remove the needle and apply a bandage to the skin puncture site.

OLDER CHILDREN

The positioning of the older child is similar to that of the neonate or infant (**Figure 174-2B**). The procedure is similar to that of the infant although it is more important to identify the location of the distended bladder to assure successful aspiration. The use of US is recommended to assist in determining the proper needle insertion site. **The urinary bladder of the older child may be in the abdomen or may have migrated into the pelvis.** The technique is similar to neonates and infants if the bladder is in the abdomen or that of adolescents and adults if the bladder is in the pelvis.

ADOLESCENTS & ADULTS

Place the patient supine. Identify the bladder by palpation or ultrasonography. Identify the needle insertion site in the midline and 2 to 4 cm cephalad of the pubic symphysis. Inject 1 to 3 mL of local anesthetic solution subcutaneously and into the abdominal wall musculature at the needle insertion site.

Place a 3 inch, 22 to 24 gauge spinal needle onto a 10 mL syringe. Insert the needle through the anesthetized skin and at a 60° angle to the skin of the abdominal wall (**Figure 174-5**). Advance the needle caudally while applying negative pressure to the syringe. Stop advancing the needle when urine is aspirated. If no urine is aspirated, withdraw the needle to the subcutaneous tissue and readvance it in a slightly different direction (e.g., 50° to the skin of the abdominal wall). After urine is obtained, remove the needle and apply a bandage to the skin puncture site.

ULTRASOUND GUIDANCE

Bedside US imaging can ensure there is sufficient urine to aspirate, confirm the anatomic location of the bladder, help guide needle placement, and decrease complications.²³⁻²⁹ It is especially helpful

FIGURE 174-4. Suprapubic bladder aspiration in the neonate and infant. **A.** Digital pressure on the urethral meatus will prevent micturition in the female. **B.** Digital pressure on the glans penis will prevent micturition in the male.

FIGURE 174-5. Suprapubic bladder aspiration in the adolescent and adult.

in infants and toddlers who have smaller bladders. There are no contraindications to using ultrasound other than those for the procedure itself. For adults, a general-purpose curvilinear abdominal or phased-array transducer provides the best combination of penetration and field of view. A linear transducer could be used for children.

Either a static or dynamic (i.e., real-time) technique can be used. The static technique involves visualizing the bladder to confirm its size, bladder location, and needle insertion site. However, the actual needle insertion is then done blindly. The dynamic technique is preferred as it allows real-time visualization of the urinary bladder, needle, and surrounding structures while the needle is advanced. The dynamic technique is not only safer, but also increases the success rate for small bladders with minimal urine. The dynamic technique can be further divided into two approaches, out-of-plane and in-plane, depending on the orientation of the US transducer to the needle.

OUT-OF-PLANE US TECHNIQUE

The out-of-plane US technique involves obtaining a transverse view of the bladder while advancing the needle in the sagittal plane of the patient's body (**Figure 174-6**). Because it is perpendicular to the transducer, the needle will be seen in its short axis on the US monitor and appear as a hyperechoic dot. The benefit of this technique is that the needle does not have to be perfectly aligned with the transducer and you are able to see structures adjacent to the bladder bilaterally. The downside to this technique is that it cannot always reliably determine where the tip of the needle is because the needle will appear as a "dot" on the US monitor regardless of which part of the needle is in view (**Figure 174-7**).

To perform the out-of-plane technique, first image the bladder to ensure there is sufficient urine to aspirate. The bladder will appear black or anechoic (**Figure 174-8**). Prepare the skin, apply sterile US gel to the patient's skin, and apply a sterile US transducer cover. Stand to the side of the patient so that your dominant hand is cephalad (**Figure 174-9**). Position the US monitor on the

FIGURE 174-6. The spinal needle is inserted under the cephalic side of the transversely oriented US transducer and angled caudally. Note, the US transducer cover and sterile gloves have been removed for clarity and should be used during the procedure.

FIGURE 174-7. Transverse US appearance of the spinal needle. The hyperechoic needle tip (arrow) is visible with a small ring-down (bright shadow) artifact immediately below it.

FIGURE 174-8. Transverse US view of the bladder.

FIGURE 174-9. The US machine is positioned in the same sight-line as the procedure. The physician's dominant (right) hand is cephalad and controls the needle. Note, the US transducer cover and sterile gloves have been removed for clarity and should be used during the procedure.

opposite side of the patient so that it is easy to see (**Figure 174-9**). Place the transducer in a transverse orientation just above the pubic symphysis. Angle the transducer caudally to view the largest anterior-posterior diameter of the bladder. Move the transducer left and right on the patient as needed to center the bladder on the US monitor.

Place the procedure needle with a 10 mL syringe in the midline of the transducer and angled caudally. The needle entry site may need to be slightly above the transducer, depending on the body habitus of the patient and depth of soft tissues superficial to the

FIGURE 174-10. The spinal needle is inserted under the cephalic side of the longitudinally oriented US transducer and angled caudally. Note, the US transducer cover and sterile gloves have been removed for clarity and should be used during the procedure.

bladder, so that as it enters the bladder it traverses the plane of the US beam. Insert the needle slowly and advance it while monitoring its trajectory on the US monitor. If the needle is a small gauge and the US transducer is low frequency, the needle will not necessarily be visible in the superficial tissue planes. Look for movements in the tissue as the needle is advanced. Once the needle crosses the plane of the US beam, it will appear as an echogenic dot with a posterior repeating artifact or shadow (**Figure 174-7**). Aspirate as the needle is advanced. Aspiration should result in urine return when the needle enters the bladder. Remove the US transducer once urine is aspirated. The remainder of the procedure can proceed as previously described.

IN-PLANE US TECHNIQUE

The in-plane US technique involves obtaining a sagittal, or long axis, view of the bladder while also aligning the needle in the sagittal plane of the patient's body (**Figure 174-10**). The entire shaft of the needle will be seen on the US monitor because it is parallel to the plane of the transducer (**Figure 174-11**). The

A

B

FIGURE 174-11. Longitudinal (sagittal) US appearance of the bladder with in-plane view of the needle. **A.** The anterior bladder wall is tenting as the needle tip is about to penetrate the wall. The remainder of the needle is not visible within the tissues. **B.** The needle is within the bladder. (Courtesy of Andrew Shedd, MD.)

benefit of this technique is that the entire needle, including its tip, is visualized ensuring proper placement within the bladder. The challenge with this technique is that it requires near-perfect alignment of the needle within the narrow plane of the US transducer (Figure 174-11).

First image the bladder to ensure there is sufficient urine to aspirate. Prepare the skin, apply sterile US gel to the patient's skin, and apply a sterile US transducer cover. Stand to the side of the patient so that your dominant hand is cephalad (Figure 174-9). Position the US monitor on the opposite side of the patient so that it is easy to see (Figure 174-9). Place the US transducer in the sagittal plane above the pubic symphysis. Move the transducer left and right on the patient as needed to center the bladder on the US monitor. An important tip to remember is that the transducer orientation indicator is on the traditional left side of the US monitor. Orient the indicator on the transducer to the left so that transducer movements on the patient correspond to the direction of motion on the US monitor.

Place the procedure needle with a 10 mL syringe in the midline of the transducer and angled caudally (Figure 174-10). The needle should be parallel to and directly under the US transducer. Insert the needle and slowly advance it. Visually ensure the needle is parallel to the transducer. Adjust the transducer side-to-side as needed to visualize the needle on the US monitor. **Avoid the rectus muscles and inferior epigastric vessels.** Aspirate as the needle is advanced. The tip of the needle will be seen tenting the anterior wall of the bladder as it penetrates the bladder (Figure 174-11A). The entire shaft of the needle, including the point, will be visible on the US monitor as it enters the bladder (Figure 174-11B). Aspiration should result in urine return when the needle enters the bladder. Remove the US transducer once urine is aspirated. The remainder of the procedure can proceed as previously described.

ASSESSMENT

If the first attempt at aspiration is unsuccessful, withdraw the needle to a subcutaneous position and redirect it at a different angle. **This should be done only if the bladder is clearly identified.** If the procedure is unsuccessful on the second attempt, the procedure should be delayed until the bladder is more distended. Consultation with a Urologist may be necessary.

AFTERCARE

No specific care is required after performing a suprapubic bladder aspiration. **Microscopic hematuria can occur following the procedure although gross hematuria is uncommon.** The patient may complain of mild pain or soreness in the suprapubic area. This can be relieved with acetaminophen or nonsteroidal anti-inflammatory drugs. The patient, if discharged, should be given specific instructions to return immediately if they develop gross hematuria, abdominal pain, fever, nausea, vomiting, or an infection at the puncture site.

COMPLICATIONS

Numerous complications can be associated with suprapubic bladder aspiration.¹⁻³² Fortunately, these are rare occurrences. Bowel perforation, intraabdominal visceral injury, uncontrolled hemorrhage, and needle misplacement are the major complications of suprapubic bladder aspiration. Infectious complications include abdominal wall cellulitis, abdominal wall abscess, sepsis, and peritonitis. Hematomas of the abdominal wall, bladder wall, and pelvis are usually self-limited and require no treatment.

In the unfortunate situation when bowel contents or continuous blood is aspirated, the appropriate surgical consultant should be contacted. Generally, simple penetration of the bowel is considered harmless and requires no specific treatment. Observe the patient for the development of signs and symptoms of peritonitis.

To avoid complications, it is key that the bladder be clearly identified prior to inserting the spinal needle. The use of ultrasonography may aid in substantial reduction of complications arising from needle misadventure. The use of strict aseptic technique should avoid most infectious complications. Delaying the procedure for infants who have urinated within the last hour and the correction of any bleeding diathesis before performing the procedure can help avoid complications.

Do not mistake ascites as urine on ultrasonography. Ascites will outline the bowel and appears in many places around the abdomen. Fluid in the bladder has rounded borders and is localized. It is easy to lose sight of the needle tip and misdirect the needle as it advances through the tissue. Always move the US transducer to keep the tip of the needle in sight. Sometimes the needle may not be visible. Look for tissue movement.

SUMMARY

In those clinical situations when transurethral urine collection is not desired or possible, suprapubic bladder aspiration is an alternative. A thorough understanding of the anatomy of the pelvic and abdominal regions, along with a complete history and physical examination, is necessary to assure patient safety and avoid complications. This procedure is a safe and effective means to obtain urine as long as the bladder can be properly identified by palpation, percussion, or ultrasonography. Suprapubic bladder aspiration provides urine that is free from urethral contamination.

Suprapubic Bladder Catheterization (Percutaneous Cystotomy)

Richard Dean Robinson, Aaron Bull, and Andrew Shedd

INTRODUCTION

Complaints involving the lower genitourinary system are among the most common urologic problems encountered by Emergency Physicians. The collection and evaluation of urine play a critical role in the process of diagnosis and treatment. Volitional voiding and transurethral urinary catheterization (Chapter 173) are the preferred methods of bladder drainage and can be accomplished in most instances. There are situations when the transurethral route

is contraindicated or technically not possible and alternate methods must be explored. A percutaneous approach to urinary bladder drainage and decompression becomes the solution, offering both therapeutic and diagnostic results.¹⁻¹¹ Suprapubic bladder catheterization has been used for decades as an effective means of accessing the bladder.

Suprapubic bladder catheterization, or percutaneous cystostomy, has become the treatment of choice for patients with acute urinary retention regardless of the cause. It is commonly performed in the trauma patient with a known or suspected urethral injury. The catheters are well tolerated, easy to care for, and can easily be replaced and/or removed. The placement of a suprapubic catheter into the bladder is fast and may be performed under local anesthesia. It is a relatively safe procedure but does have potential complications that are significant.

ANATOMY AND PATHOPHYSIOLOGY

Residing in the retropubic space, approximately 5 cm above the superior margin of the symphysis pubis, the adult urinary bladder has both retroperitoneal and intraperitoneal attachments. A working knowledge of this anatomy makes percutaneous bladder manipulation both safe and possible. The rectum lies just inferior and posterior to the urinary bladder. This relationship must be kept in mind when attempting percutaneous access. The bladder dome has peritoneal attachments and access in this area carries a risk of bowel injury and intraperitoneal bladder perforation. Multiple vascular structures, including the common iliac and hypogastric vessels, reside in the bony pelvis alongside the bladder. These structures are lateral to the bladder and eccentric (i.e., off the midline) percutaneous access may result in iatrogenic injury and hemorrhage.

INDICATIONS

Suprapubic bladder catheterization is indicated in cases when the transurethral route of bladder drainage or decompression is technically not possible or contraindicated.^{9,12,13} This includes patients with bladder neck injuries and lesions, enlarged prostates (e.g., benign hypertrophy or cancer), iatrogenic urethral injuries, intractable urinary incontinence, obstructing urethral lesions, neurologic disease, an obstructing phimosis, palliative care, post-operation, suspected or known traumatic urethral or prostatic disruption, a urethral foreign body, urethral scarring, and/or urethral strictures. Continuous bladder irrigation can be accomplished via a combined suprapubic and transurethral route. Long-term bladder drainage is the final indication for a suprapubic bladder catheterization.¹⁴

CONTRAINDICATIONS

Suprapubic catheterization is absolutely contraindicated in the absence of an easily palpable and distended or ultrasonographically localized and distended urinary bladder.⁹ Under no circumstances should “blind” percutaneous access be attempted. The bladder must be distended to push the bowel away from the anterosuperior surface of the bladder to avoid perforating the bowel.

Patients with a coagulopathy are at an increased risk for significant hemorrhage from any percutaneous procedure including suprapubic bladder catheterization. Any coagulopathy, bleeding diathesis, platelet dysfunction, and/or thrombocytopenia should be corrected prior to performing this procedure.

Other absolute contraindications exist. The peritoneal cavity has been violated and the bowel may be displaced more caudally and to the level of the urinary bladder in individuals with prior lower abdominal surgery or traumatic injury. The bowel may be adhered

to the anterior abdominal wall. This heightens the risk of inadvertent entry into the peritoneal cavity and bowel injury. It should not be placed in patients with abdominal wall infections, bladder cancer, or subcutaneous vascular grafts in the suprapubic region.

There are many relative contraindications to percutaneous bladder catheterization. These include patients who have ascites, patients with a history of pelvic cancer or pelvic radiation therapy, uncooperative patients, or patients who have urinary tract infections. A history of pelvic cancer or irradiation will increase the risk of adhesions, anatomic distortion, and scarring. Attempts at suprapubic cystostomy increase the risk of peritoneal and/or bowel perforation. The return of ascitic fluid may lead the Emergency Physician to a false sense of security when the catheter is actually intraperitoneal. Urine leakage in patients with a urinary tract infection may result in bacteremia, peritonitis, and/or sepsis. In these circumstances, consult a Urologist for an open suprapubic cystostomy or Interventional Radiology for a percutaneous cystostomy using fluoroscopic or ultrasonographic guidance. An uncooperative patient will require parenteral sedation or procedural sedation (Chapter 159) prior to performing this procedure. Any extremity contractures, physical alterations, spinal deformities, truncal obesity, or other conditions that would preclude the patient from lying supine and inhibit bladder palpation are also relative contraindications to performing a percutaneous cystostomy.

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- Sterile gloves
- Percutaneous cystostomy catheter kit
- Foley catheter, 14 to 16 French
- 60 mL catheter-tipped syringe
- 10 mL syringes
- 24 to 25 gauge spinal needle, 3 inches long
- #11 surgical scalpel blade on a handle
- 3–0 nylon suture
- Needle driver
- Local anesthetic solution, with or without epinephrine
- 4×4 gauze squares
- 25 gauge needle, 1 inch long
- 18 gauge needle
- Urine meter or urine leg bag
- Sterile towels
- Sterile drapes
- Tincture of benzoin
- 2 inch tape
- Ultrasound machine (recommended)
- Sterile ultrasound gel
- Sterile ultrasound transducer cover
- Curvilinear abdominal or phased-array transducer for adults
- Linear transducer for children

The percutaneous cystostomy catheter kit is commercially available and prepackaged by several manufacturers.¹⁵ One type contains a cystostomy tube, an obturator, and connector tubing (Figures 175-1 and 175-2). Another is a Seldinger-type kit with peel-away sheath.

A commonly used suprapubic catheter kit is the Rutner Percutaneous Suprapubic Balloon Catheter Set as seen in Figure 175-2

FIGURE 175-1. Schematic of a catheter and obturator system. **A.** The catheter. **B.** The obturator. **C.** The obturator within the catheter.

(Cook Urological Inc., Spencer, IN).¹⁵ It consists of a 10 French catheter that is 22 cm long, a needle obturator, a connecting tube, and a 3 mL syringe (Figures 175-1 and 175-2A). The proximal end of the catheter has two ports (Figures 175-1 and 175-2B). One port is for the insertion of the obturator through the catheter. The obturator screws and locks into this port. The other port is an inflation port for the cuff of the catheter. A 3 to 5 mL syringe attaches to this port. The obturator is a hollow tube that tapers to a sharp point distally. When properly inserted and locked into the port, the obturator will project 2.5 mm from the distal end of the catheter (Figures 175-1C and 175-2C). The cuff is donut-shaped and centered 1 cm from the tip of the catheter (Figure 175-2D). The connector tube has a stopcock at its distal end that attaches to the catheter (Figure 175-2E). The proximal end of the connector tube has a flared flange to attach to a urine drainage system.

PATIENT PREPARATION

As with all procedures, the risks and benefits of suprapubic bladder catheterization should be discussed with the patient and/or their representative. Obtain an informed consent and place it in the medical record.

Place the patient supine. Clean any dirt and debris from the abdominal wall. Shave the lower abdomen if the patient is hirsute. Identify the bladder by palpation, percussion, and/or ultrasonography. Apply povidone iodine or chlorhexidine solution to the lower abdomen, from the umbilicus to the pubis, and allow it to dry. Consider the administration of parenteral analgesics, sedatives, or procedural sedation (Chapter 159) as this is a painful procedure.

Anesthetize the abdominal wall. Fill a 10 mL syringe with local anesthetic solution. Apply a 24 to 25 gauge spinal needle onto the syringe. Identify the insertion site in the midline and 4 to 5 cm above the pubic symphysis. The use of ultrasound to verify the

The distal end has a flared flange (as seen in figure **A**).

bladder location and to ensure that no loops of bowel are present between the abdominal wall and bladder is recommended.⁹ Make a skin wheal with the local anesthetic solution at the insertion site. Insert the spinal needle at a 60° to 70° angle to the skin and aimed caudally (**Figure 175-3A**). Advance the needle through the subcutaneous tissue, rectus sheath, and retropubic space while simultaneously aspirating and injecting 5 to 10 mL of local anesthetic solution. A loss of resistance will be felt as the spinal needle traverses the rectus sheath and enters the retropubic space. Continue to aspirate while advancing the spinal needle until the bladder is entered and urine fills the syringe. The bladder appears to tent as the needle pierces its anterior wall when ultrasonographic guidance is used.⁸ **Note the needle direction and depth of insertion required to enter the bladder.**

TECHNIQUES

SELDINGER TECHNIQUE WITH A PEEL-AWAY SHEATH

This method is similar to that of placing a central venous catheter. The needle is used to locate the bladder. Place the needle on a 10 mL syringe. Insert the needle through the skin wheal of local anesthetic solution located in the midline and 4 to 5 cm above the pubic symphysis. Direct the needle caudally and at a 60° to 70° angle to the skin (**Figure 175-3A**). **It is important to ensure that the needle enters and is advanced in the midline. This area is avascular. If the needle is paramedian it may traverse the rectus muscles and inferior epigastric vessels, resulting in significant hemorrhage.**

FIGURE 175-3. The Seldinger technique with a peel-away sheath. **A.** The finder needle is inserted 60° to 70° to the skin and advanced into the bladder. **B.** The syringe has been removed and the guidewire inserted through the needle. **C.** The needle has been removed. The dilator and peel-away sheath are inserted over the guidewire as a unit and into the bladder. **D.** The dilator and guidewire are removed. **E.** The peel-away sheath remains through the skin and into the bladder. **F.** A Foley catheter is inserted through the peel-away sheath and into the bladder. **G.** Urine is aspirated from the bladder. The cuff on the catheter has been inflated. **H.** The arms of the peel-away sheath are pulled upward and apart to remove the sheath. **I.** The cuff is lodged against the dome of the bladder.

Advance the needle caudally while applying negative pressure with the syringe. Stop advancing the needle when urine is aspirated into the syringe. Advance the needle an additional 2 to 3 cm into the bladder from the point at which urine is initially aspirated into the syringe. The aspiration of urine will confirm the proper position of the needle within the bladder.

Firmly hold the needle against the abdominal wall. Carefully remove the syringe from the needle. **Do not allow the needle to move as it may shear the bladder wall.** Advance the guidewire through the needle and into the bladder (**Figure 175-3B**). Withdraw the needle over the guidewire while leaving the guidewire in place. Make a superficial stab incision with the #11 scalpel blade adjacent to the guidewire. This will facilitate passage of the dilator and sheath through the abdominal wall. Insert the dilator through the peel-away sheath. Advance the dilator and peel-away sheath as a unit over the guidewire and into the bladder (**Figure 175-3C**). Remove the guidewire and dilator as a unit (**Figure 175-3D**) leaving only the peel-away sheath (**Figure 175-3E**).

Insert a Foley catheter through the peel-away sheath and completely into the bladder (**Figure 175-3F**). The Foley catheter should be two sizes (i.e., 2 French) smaller than the size of the peel-away sheath. Urine should flow spontaneously from the Foley catheter. If not, insert a 60 mL catheter-tipped syringe into the Foley catheter and aspirate (**Figure 175-3G**). The flow of urine will confirm that the catheter is properly positioned within the bladder. Inflate the cuff of the Foley catheter. Attach a urine collection system to the proximal end of the Foley catheter (**Figure 175-3H**).

Remove the peel-away sheath. Grasp the free ends or arms of the peel-away sheath. Pull the free ends upward and opposite each other (**Figure 175-3H**). The peel-away sheath will split in half as it is withdrawn over the Foley catheter and out of the abdominal wall. Gently withdraw the Foley catheter to ensure that the cuff is lodged against the bladder wall (**Figure 175-3I**).

OBTURATOR TECHNIQUE

The trochar technique has been used for many years.¹⁶ The obturator technique is a derivative of the trochar technique. Prepare the equipment. Insert the obturator through the catheter and lock it in position. Inflate the cuff with sterile saline and check its integrity. Deflate the cuff. Inflate and deflate the cuff two more times to soften the cuff. The spinal needle was previously used to infiltrate local anesthetic solution and locate the urinary bladder. This maneuver allows the operator to determine both the depth and angle needed for bladder entry.

Make a 3 to 4 mm stab incision in the midline and 4 to 5 cm above the pubic symphysis through the skin wheal of local anesthetic solution with a #11 scalpel blade. Place the tip of the obturator-catheter unit in the skin incision. **It is important to ensure that the unit enters and is advanced in the midline. This area is avascular. If the unit is paramedian, it may traverse the rectus muscles and inferior epigastric vessels resulting in significant hemorrhage.** Direct the unit caudally and at a 60° to 70° angle to the skin (**Figure 175-4A**). Place the nondominant hand on the lower abdominal wall. Grasp the tip of the obturator-catheter unit with the thumb and index finger of the dominant hand. The hand and fingers will stabilize the unit and control the depth of insertion.

Advance the obturator-catheter unit with the dominant hand. Resistance may be felt as the trocar traverses the linea alba. Apply firm pressure to the unit to advance through the linea alba. **Do not plunge as the unit is advanced.** Continue to advance the unit through the retropubic space until resistance is felt. The tip of the trocar is now against the anterior bladder wall. Advance the unit with a short and rapid stabbing motion to enter the bladder (**Figure 175-4A**). Urine should flow spontaneously from the

proximal end of the obturator. If not, attach a syringe to the obturator and aspirate. The flow of urine will confirm that the tip of the obturator-catheter unit is properly positioned within the bladder. Advance the unit an additional 2 to 3 cm into the bladder to ensure the cuff is completely within the bladder.

Inflate the cuff of the catheter (**Figure 175-4B**). Unscrew the obturator from the catheter. Securely hold the catheter, with the nondominant hand as it exits the abdominal wall. Remove the obturator from the catheter (**Figure 175-4C**). Attach the stopcock at the distal end of the connector tube to the catheter (**Figure 175-4D**). Gently withdraw the catheter to lodge the cuff against the bladder wall. Attach a urine collection system to the proximal end of the connector tube.

ULTRASOUND GUIDANCE

Bedside ultrasound (US) imaging can ensure there is sufficient urine to aspirate, confirm the anatomic location of the bladder, help guide needle placement, and decrease complications.¹⁷⁻²² It is especially helpful in infants and toddlers who have smaller bladders. There are no contraindications to using US other than those for the procedure itself. For adults, a general-purpose curvilinear abdominal or phased-array transducer provides the best combination of penetration and field of view. A linear transducer could be used for children.

Either a static or dynamic (i.e., real-time) technique can be used. The static technique involves visualizing the bladder to confirm its size, bladder location, and needle insertion site. However, the actual needle insertion is then done blindly. The dynamic technique is preferred as it allows real-time visualization of the urinary bladder, needle, and surrounding structures while the needle is advanced. The dynamic technique is not only safer, but also increases the success rate for small bladders with minimal urine. The dynamic technique can be further divided into two approaches, out-of-plane and in-plane, depending on the orientation of the US transducer to the needle.

OUT-OF-PLANE ULTRASOUND TECHNIQUE

The out-of-plane US technique involves obtaining a transverse view of the bladder while advancing the needle in the sagittal plane of the patient's body (**Figure 175-5**). Because it is perpendicular to the transducer, the needle will be seen in its short axis on the US monitor and appear as a hyperechoic dot. The benefit of this technique is that the needle does not have to be perfectly aligned with the transducer and you are able to see structures adjacent to the bladder bilaterally. The downside to this technique is that it cannot always reliably determine where the tip of the needle is because the needle will appear as a "dot" on the US monitor regardless of which part of the needle is in view (**Figure 175-6**).

To perform the out-of-plane technique, first image the bladder to ensure there is sufficient urine to aspirate. The bladder will appear black or anechoic (**Figure 175-7**). Prepare the skin, apply sterile US gel to the patient's skin, and apply a sterile US transducer cover. Stand to the side of the patient so that your dominant hand is cephalad (**Figure 175-8**). Position the US monitor on the opposite side of the patient so that it is easy to see (**Figure 175-8**). Place the transducer in a transverse orientation just above the pubic symphysis. Angle the transducer caudally to view the largest anterior-posterior diameter of the bladder. Move the transducer left and right on the patient as needed to center the bladder on the US monitor.

Place the procedure needle with a 10 mL syringe in the midline of the transducer and angled caudally. The needle entry site may need to be slightly above the transducer depending on the body habitus of the patient and depth of soft tissues superficial to the bladder

FIGURE 175-4. The obturator technique. **A.** The obturator is within the catheter. The system is inserted 60° to the skin and advanced into the bladder. **B.** The cuff is inflated. **C.** The obturator is removed while the catheter remains within the bladder. **D.** The catheter has been pulled upward and the collecting tube is attached to the catheter.

FIGURE 175-5. The spinal needle being inserted out-of-plane under the cephalic side of the transversely oriented US transducer and angled caudally. Note, the US transducer cover and sterile gloves have been removed for clarity and should be used during the procedure.

so that as it enters the bladder as it traverses the plane of the US beam. Insert the needle slowly and advance it while monitoring its trajectory on the US monitor. If the needle is a small gauge and the US transducer is low frequency, the needle will not necessarily be visible in the superficial tissue planes. Look for movements in the tissue as the needle is advanced. Once the needle crosses the plane of the US beam, it will appear as an echogenic dot with a posterior repeating artifact or shadow (**Figure 175-6**). Aspirate as the needle is advanced. Aspiration should result in urine return when the needle enters the bladder. Remove the US transducer once urine is aspirated. The remainder of the procedure for the Seldinger technique can proceed as previously described. The US procedure is the same if using the obturator technique; simply substitute the catheter-obturator unit for the needle described above.

IN-PLANE ULTRASOUND TECHNIQUE

The in-plane US technique involves obtaining a sagittal, or long axis, view of the bladder while also aligning the needle in the sagittal

FIGURE 175-6. Transverse US appearance of the bladder and spinal needle as the spinal needle is oriented out-of-plane. The hyperechoic needle tip (arrow) is visible with a small ring-down (bright shadow) artifact immediately below it.

FIGURE 175-7. Transverse US view of the bladder.

plane of the patient's body (**Figure 175-9**). The entire shaft of the needle will be seen on the US monitor because it is parallel to the plane of the transducer (**Figure 175-10**). The benefit of this technique is that the entire needle, including its tip is visualized ensuring proper placement within the bladder. The challenge with this technique is that it requires near-perfect alignment of the needle within the narrow plane of the US transducer (**Figure 175-10**).

First image the bladder to ensure there is sufficient urine to aspirate. Prepare the skin, apply sterile US gel to the patient's skin, and apply a sterile US transducer cover. Stand to the side of the patient so that your dominant hand is cephalad (**Figure 175-8**). Position the US monitor on the opposite side of the patient so that it is easy to see (**Figure 175-8**). Place the US transducer in the sagittal plane above the pubic symphysis. Move the transducer left and right on the patient as needed to center the bladder on the US monitor.

FIGURE 175-8. The US machine is positioned in the same sight line as the procedure. The physician's dominant (right) hand is cephalad and controls the needle. Note, the US transducer cover and sterile gloves have been removed for clarity and should be used during the procedure.

FIGURE 175-9. The spinal needle being inserted in-plane under the cephalic side of the longitudinally oriented US transducer and angled caudally. Note, the US transducer cover and sterile gloves have been removed for clarity and should be used during the procedure.

An important tip to remember is that the transducer orientation indicator is on the traditional left side of the US monitor. Orient the indicator on the transducer to the left so that transducer movements on the patient correspond to the direction of motion on the US monitor.

Place the procedure needle with a 10 mL syringe in the midline of the transducer and angled caudally (**Figure 175-9**). The needle should be parallel to and directly under the ultrasound transducer. Insert the needle and slowly advance it. Visually ensure the needle is parallel to the transducer. Adjust the transducer side-to-side as needed to visualize the needle on the US monitor. **Avoid the rectus muscles and inferior epigastric vessels.** Aspirate as the needle is advanced. The tip of the needle will be seen tenting the anterior wall of the bladder as it penetrates the bladder (**Figure 175-10A**). The

entire shaft of the needle, including the point, will be visible on the US monitor as it enters the bladder (**Figure 175-10B**). Aspiration should result in urine return when the needle enters the bladder. Remove the US transducer once urine is aspirated. The remainder of the procedure for the Seldinger technique can proceed as previously described. The US procedure is the same if using the obturator technique; simply substitute the catheter-obturator unit for the needle described above.

ASSESSMENT

The return of urine confirms the correct placement of the catheter into the bladder. If the catheter ceases to work after initially functioning properly, inspect the portion outside of the patient's body for kinks.²³ Flush the catheter with sterile saline to remove any potential clots. A catheter that flushes easily but cannot be subsequently aspirated suggests that the tip has been withdrawn into the perivesicular space of the pelvic cavity or that the catheter is kinked. The catheter is kinked if saline cannot be flushed through or aspirated. The catheter is properly positioned within the bladder if saline flushes and aspirates without difficulty. Consider the use of US to confirm catheter placement and the presence of urine within the bladder.

AFTERCARE

Secure the catheter to the abdominal wall (**Figure 175-11**). Place 4×4 gauze squares over the pubic symphysis to bolster the catheter as it exits the abdominal wall. Apply tincture of benzoin to the abdominal wall and allow it to dry. Tape over the catheter and gauze. The ends of the tape should be applied to the dried benzoin solution. Prophylactic antibiotics are not required unless a urinary tract infection is present.

Examine the puncture site twice a day for any signs of infection. Routine wound care should be performed at the puncture site. If removed within 7 days, the bladder wall and abdominal wall will heal without complications. A transurethral catheter should be inserted to ensure urine egress through the urethra and not the bladder wall while the suprapubic catheter tract heals. After 10 to 14 days, the tract of the catheter is epithelialized and mature. The catheter may be exchanged through the mature tract if necessary. Suprapubic tubes should not be left in place for more than 4 weeks.⁹

The remainder of the needle is not visible within the tissues. **B.** The needle is within the bladder. (Courtesy of Andrew Shedd, MD.)

FIGURE 175-11. Securing the catheter.

COMPLICATIONS

Bowel perforation, catheter migration, catheter misplacement, intraabdominal visceral injury, peritonitis, uncontrolled hemorrhage and vascular injury are the major complications of a suprapubic cystostomy catheter placement.^{1-9,24-26} Perforation of the bowel can be prevented by ensuring that the bladder is distended by palpation, percussion, or ultrasonography. Intraperitoneal perforation is more common in patients with ascites, a distended abdomen, or prior abdominal surgery. Gross hematuria is common and transient. Through-and-through perforation of the bladder can injure the rectum, vagina, and/or uterus. Other minor complications are associated with the length of indwelling catheter time and include bleeding, infections (e.g., cellulitis and abscesses), kinking, and stone formation.²³

When catheter placement is in doubt or when a previously draining tube no longer continues to drain, simple flushing and irrigation will usually suffice. Bedside US is a quick means to confirm catheter placement. However, if concern persists, a gravity cystogram under fluoroscopy can be diagnostic. In the unfortunate situation when bowel contents or continuous blood is aspirated or flows from the catheter, the appropriate surgical consultations should be obtained.

SUMMARY

Suprapubic bladder access is the preferred alternative in those clinical situations when transurethral bladder decompression is no longer an option. Years of experience demonstrate suprapubic bladder catheterization to be an effective and relatively safe method of accessing the bladder. A prior understanding of the associated anatomy is paramount to avoidance of adverse results.

Retrograde Urethrography and Cystography

Richard Dean Robinson and Sasha Michael Dib

INTRODUCTION

Urinary tract injuries may result from blunt trauma, penetrating trauma, urologic procedures, or may arise spontaneously.¹⁻¹⁴ Bladder injuries occur in up to 15% of pelvic fractures.¹⁻³ Associated urethral injuries occur in up to 11% of males and up to 6% of females.¹⁻³ **The role of retrograde urethrography and cystography in evaluation of the trauma patient is to rule out a partial urethral rupture,**

complete urethral rupture, and/or bladder rupture.¹⁵⁻¹⁷ On initial presentation to the Emergency Department, there are clear indications for performing these procedures. The importance of proper training in these techniques must be stressed to avoid secondary injury.

The evaluation of trauma patients should include, if appropriate, an assessment of the bony pelvis and the genitourinary system. The identification of a pelvic fracture must be followed by an examination of the lower genitourinary tract to rule out an associated injury. Patients with disruption of the pubic symphysis or pubic rami or with a vertically unstable pelvic fracture have a high incidence of concomitant bladder trauma.¹³ Patients with an isolated acetabulum, femur, or iliac crest fracture have a low incidence of bladder injury or rupture.¹³ **The lack of a pelvic fracture does not eliminate the possibility of a bladder or urethral injury.** The most common signs seen with genitourinary tract injury are gross hematuria (82%) and abdominal tenderness (62%).⁴ Other signs of genitourinary tract injury include blood at the urethral meatus, the inability to void, swelling or ecchymosis of the perineum or penis, a boggy prostate, and a high-riding prostate. An evaluation of the genitourinary tract is indicated in the presence of any of these signs. These assessments should be made early and interventions instituted immediately.

Traditional teaching suggests that urethral catheterization should be avoided if a potential injury to the bladder and/or urethra is suspected. This teaching requires performance of a retrograde urethrogram and cystogram to rule out any injuries prior to urethral catheterization. A preliminary study suggests that blind urethral catheterization, despite a potential injury, may be safe.¹⁸ Additional large multicenter studies are required before this change in practice can be safely recommended. The guidelines do allow for a single attempt at catheter drainage if exceptional circumstances indicate a need for monitoring.¹⁴

ANATOMY AND PATHOPHYSIOLOGY

The lower urinary tract in males consists of the urethra and bladder (**Figure 176-1**). The urethra is divided into the fossa navicularis, the penile urethra, the bulbar urethra, the membranous urethra, and the prostatic urethra based on anatomic location. The bladder neck opens into the trigonal canal and funnels into the bladder. The male posterior urethra is 5.0 to 5.5 cm long, fixed to the urogenital diaphragm, and the area most susceptible to injury.^{2,5} The female urethra is short, not rigidly fixed to the pubis or pelvic floor, mobile, and much less susceptible to injury.³ The female urethra is

equivalent to the membranous and prostatic (i.e., posterior) urethra in the male.⁶

The periurethral striated sphincter is composed of muscle from the urogenital diaphragm. This muscle layer unites with the distal smooth muscle at the intermuscular incisura. This is frequently seen on the voiding cystourethrogram and may be mistaken for a stricture or posterior urethral valves. The urogenital diaphragm surrounds the membranous urethra and may compress the urethra during voiding or on retrograde flow of contrast.⁶

The verumontanum and urethral crest protrude into the male prostatic urethral lumen and may extend into the membranous urethra. The prostatic gland ducts, prostatic utricle, ejaculatory ducts, and urethral gland ducts usually do not fill on voiding cystourethrogram; and when visible, filling usually denotes distal obstruction. These structures may also fill from aggressive injection of contrast during the retrograde urethrogram.

The anterior and posterior baseplates, of which the trigone is part, are seen as a diagonal plane sloping downward from posterior to anterior on the lateral view of the bladder. The bladder neck is visualized at the junction of the anterior one-third and the posterior two-thirds of the plane. Anteriorly the pubis abuts the baseplate. The fundus of the bladder becomes more dome-shaped as it fills with fluid. It may be compressed by the uterus or colon in the midline or on either side.⁶

INDICATIONS

The retrograde urethrogram should be employed in males presenting with blunt and penetrating trauma when there is any indication of a urethral injury. Indications include penetrating injury when involvement of the lower genitourinary tract is suspected, pelvic fractures, perineal or lower abdominal trauma with gross hematuria, vaginal lacerations, sacral spine fractures, blood at the urethral meatus, the inability to void, swelling of the perineum or penis, ecchymosis of the perineum or penis, hematoma of the perineum or penis, a high-riding prostate, or a boggy prostate.^{7,8,13,19,20} Other indications include urethral strictures and obstructions, congenital abnormalities, periurethral or prostatic abscess, fistulae, and false passages. It may be indicated in females if urethral diverticula are suspected.

Retrograde cystography should follow retrograde urethrography, especially in patients who recall having a full bladder at the time of trauma and are later unable to void or have small amounts of bloody urine.⁹ Retrograde cystograms are nearly 100% sensitive for

FIGURE 176-1. Anatomy of the male genitourinary tract.

detecting a bladder rupture provided that adequate distension is accomplished and that postvoid images are obtained.¹³

CONTRAINDICATIONS

There are few contraindications to retrograde urethrography and cystography. The patient's overall condition must be taken into consideration. Lifesaving procedures, such as securing an airway and stabilizing life- and limb-threatening injuries, must take precedence. Because septic shock and irreversible renal damage can occur, a relative contraindication in the setting of acute urethritis exists when the suspicion of genitourinary tract trauma is very low. **A urethral injury identified on the retrograde urethrogram is the only absolute contraindication to transurethral bladder catheterization and retrograde cystography.** Consult a Urologist if, in a patient with pelvic trauma, there is any difficulty in passing a urethral catheter into the bladder. **Do not try to advance a catheter against resistance as iatrogenic injury can result.** There is a small risk of allergic reactions to the contrast media. Patients with previous reactions should receive nonionic agents and be premedicated with corticosteroids and antihistamines.

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- Sterile gloves
- Sterile drapes
- Viscous lidocaine suspension
- Foley catheter, 5 to 18 French (Table 176-1)
- Brodney clamp
- Contrast material
- 60 mL catheter tip syringe
- Toomey syringe
- Christmas tree adaptor
- Surgical clamp
- Lead apron

A variety of contrast agents are available and may be used to perform retrograde urethrography and cystography. Agents used are specific to each institution. Most commonly used are full strength Hypaque (50% diatrizoate sodium), Renografin-60 (diatrizoate sodium), or Cystografin (18% or 30% diatrizoate meglumine). Alternatively, the same agents can be diluted with sterile saline in a 1:10 (i.e., contrast to saline) solution.

PATIENT PREPARATION

Explain the procedure, its risks, and benefits to the patient and/or their representative. While a formal consent is usually not obtained since this is an emergent procedure, document in the medical record

TABLE 176-1 Estimated Foley Catheter Size Based on Patient Age

Patient age	Catheter size (French)
Premature or newborn	5
3–12 months	8
1–2 years	8–10
2–8 years	10
8–10 years	10–12
10–12 years	12
12–14 years	12–14
14+ years	16–18

that the “risks and benefits were explained to the patient.” If not contraindicated, administer parenteral sedation. Place the patient in a 45° oblique position with their left side on the bed. Flex the left leg at the knee and abduct the hip. Place a radiolucent wedge or rolled towels under the patient to maintain the oblique positioning. Completely extend the right leg. This is the ideal patient position. The degree of patient mobility and the medical condition at hand may dictate an alteration of this position. In patients with pelvic fractures, all radiographs should be taken with the patient in a supine position.

Prepare the penis and urethra. Clean any dirt and debris from around the penis. Retract the foreskin if the patient is uncircumcised. Apply povidone iodine or chlorhexidine solution to the penis and allow it to dry. Apply sterile drapes to delineate a sterile field. **The retrograde urethrogram must be performed under sterile conditions. Insert viscous lidocaine into the urethral meatus to anesthetize the urethra. Do not use lidocaine jelly as this may impede the flow of contrast material.** Allow the viscous lidocaine to remain in the urethra for 2 to 4 minutes prior to performing the procedure to provide adequate analgesia.

Obtain a flat plate or a KUB (kidney, ureters, and bladder) radiograph. This will be a baseline film for future reference. Carefully examine the radiograph for curvature of the spine, pelvic fractures, fractures of ribs 9 to 12, unilateral or bilateral loss of the normal psoas muscle shadow, and/or vertebral transverse process fractures. Any of these findings can signify a urinary tract injury. Observe and note any radiopaque material that may be present prior to the injection of contrast material.

The Emergency Physician should dress appropriately for the procedure. The Emergency Physician should wear a lead apron due to the proximity of the patient during the procedure and while radiographs are taken. Dress in a sterile gown and gloves. A cap and mask are not required.

RETROGRADE URETHROGRAPHY TECHNIQUES

FOLEY CATHETER TECHNIQUE

The Foley catheter technique is the preferred method. The Foley catheter causes little or no discomfort, is flexible, and the patient may be able to move if necessary. **Ensure there is no leakage of contrast from the urethra and onto the patient which can cause radiographic artifacts thereby making interpretation difficult.** An advantage to using the Foley catheter is that it can subsequently be advanced into the bladder to perform the cystogram. Newer types of catheters have two cuffs, one at the tip and the other near the balloon inflation hub of the catheter. The proximal cuff will expand when the pressure in the distal cuff exceeds the maximum safe pressure during cuff inflation. This allows excess pressure to be directed away from the distal cuff minimizing iatrogenic urethral injury. There are some disadvantages to this method. The inflated cuff may conceal an injury of the distal urethra at the fossa navicularis. Air bubbles are difficult to eliminate from the catheter. This may impair the flow of contrast material or produce artifacts due to air in the urethra. Air bubbles in the Foley catheter will alter the study integrity. Prime the tubing with contrast before inserting it into the urethra to eliminate any air. Place an x-ray plate under the patient's hips and pelvis.

Insert the catheter into the urethra. Advance the catheter until the cuff is within the fossa navicularis (**Figure 176-2A**). Inflate the cuff with approximately 3 mL of sterile saline or to the point that it is snug and does not cause pain to the patient.¹⁰ Gently straighten the urethra by directing the tip of the penis toward the dependent

FIGURE 176-2. Retrograde urethrography. **A.** Foley catheter technique. **B.** Syringe technique.

shoulder or nipple and over the thigh. Avoid traction on the penis or the Foley catheter as this tends to narrow the urethra and/or dislodge the catheter. Attach a contrast-filled syringe to the proximal end of the Foley catheter (**Figure 176-2A**). Gently inject 50 to 60 mL of contrast material over 5 to 10 seconds.

Obtain a plain radiograph at or near the end of the injection. Have the film developed and review the image. The entire urethra should be visible in a lateral projection. Repeat the procedure if this is not achieved. Allow the contrast to drain from the urethra through the Foley catheter and into a container. Deflate the cuff and remove the catheter from the urethra. Obtain an additional plain radiograph of the pelvis as a washout image. Have the film developed and review the image for any abnormalities in the urethra. Although not necessary, fluoroscopy may aid in obtaining an adequate study.¹⁰

Great care should be taken so as to not allow any contrast to leak out of the catheter or urethra. Any spill of contrast material will cause distortions on the radiographs. The contrast may also cause skin irritation. It should be wiped and rinsed off the skin immediately if this occurs.

SYRINGE TECHNIQUE

If a proximal urethral injury is suspected, the alternative method is to use a 60 mL catheter-tipped Toomey syringe or a 60 mL syringe with a Christmas tree adaptor. Because it is not flexible and cannot be fixed inside the penis, the syringe must be held in place at all times during the procedure. The penile shaft must also be held to secure the tip of the syringe inside the urethra. There is a significant chance of contrast leakage from the urethra using this technique.

Clean, prep, and drape the penis as described previously. Place an x-ray plate under the patient's hips and pelvis. Grasp and cradle the patient's penis with the nondominant hand. Insert the tip of the contrast-filled syringe into the urethra. Firmly squeeze the glans penis between the thumb and the index and long fingers (**Figure 176-2B**). This will secure the catheter tip within the fossa navicularis. Do not squeeze the shaft of the penis with middle, ring, or little fingers as this can occlude the urethra. Gently straighten the urethra by directing the tip of the penis toward the dependent shoulder or nipple and

over the left thigh. The remainder of the procedure is as described above in the Foley catheter section.

BRODNEY CLAMP TECHNIQUE

The Brodney clamp is a cage with rubber feet that clamp behind the corona of the glans (**Figure 176-3**).¹⁰ In the center of the device, there is a blunt-tipped obturator that inserts into and occludes the urethral meatus. It may be used instead of a Foley catheter or 60 mL syringe for the procedure. The advantage of this device is that both the fossa navicularis and the distal urethra are visible on the radiograph. Air bubbles are easily eliminated from the obturator. The disadvantages of the clamp are that it is not flexible and it is heavy. It must be held during the procedure and fluoroscopy is impossible. If the patient moves, the clamp tends to dislodge. The clamp is difficult to use in older children, adolescents, and adults and in the presence of a phimosis.¹⁰ Brodney clamps are usually not stocked in the Emergency Department and may be difficult to obtain in a timely manner.

FIGURE 176-3. The Brodney clamp.

Clean, prep, and drape the penis as mentioned previously. Insert the blunt-tipped obturator of the clamp into the urethra. Rotate the feet of the clamp so that they are grasping the coronal sulcus of the penis. These should not be so tight as to occlude the urethra ventrally. The remainder of the technique is as described in the Foley catheter section.

RETROGRADE CYSTOGRAPHY TECHNIQUE

Any abnormalities in the retrograde urethrogram, such as extravasation of contrast from the urethra or evidence of strictures, should prompt an urgent consult by a Urologist. If the study is normal, the retrograde cystogram should be performed. Gently advance and fully insert a Foley catheter into the bladder (Figures 176-4A and 176-4B). Inflate the cuff at the tip of the Foley catheter. Gently pull on the Foley catheter to lodge the cuff at the bladder neck (Figure 176-4C). Attach a 60 mL catheter-tipped syringe, without the plunger, to the Foley catheter. Pour contrast material into the syringe and let it drain by gravity to overdistend the bladder.

Continue to allow contrast to fill the bladder until 300 to 400 mL of contrast material is in the bladder of an adult or any child older than 11 years old. In younger children, the instilled volume is estimated in mL by the formula: weight (kg) \times 10 for children < 1 year of age, (age in years + 2) \times 30 for children > 1 year of age, or to the point of initiating a bladder contraction.¹¹ If a bladder contraction occurs, refill the bladder to the volume that initiated the contraction and clamp the Foley catheter. Volumes less than these can result in a false-negative study. Clamp the Foley catheter after the contrast is instilled with a hemostat.

Obtain two plain radiographs. These are the anteroposterior (AP) and the oblique, or lateral, views of the pelvis. Evaluate the radiographs for proper bladder filling with contrast and for extravasation

of contrast. Release the hemostat and allow the contrast to drain out of the bladder through the Foley catheter and into the container. Obtain another AP radiograph of the pelvis as a washout film. This film is often helpful in picking up obscured areas of extravasation not visible on the initial film. Review the radiographs for intraperitoneal and extraperitoneal bladder rupture.

COMPUTED TOMOGRAPHY (CT) CYSTOURETHROGRAPHY

CT retrograde urethrography and cystography are variations on conventional plain film cystourethrography.^{14,21} Using CT imaging may be an alternative in trauma patients requiring a CT scan of the pelvis and may reduce the time for patient evaluation. Plain film and CT imaging of the bladder are both considered appropriate methods in the evaluation of suspected bladder injury.^{22,23} Sensitivity and specificity for bladder rupture have been demonstrated to be comparable between plain film and CT modalities.^{14,24}

Performing a CT urethrogram is similar to the Foley catheter technique described previously. Place the Foley catheter into the distal urethra, inflate the balloon, and inject 10 mL of contrast material. Clamp the Foley catheter. Obtain a thin-cut CT scan through the pelvis, perineum, and penis. Instruct the CT technician to run a computerized three-dimensional reconstruction of the CT scan. Evaluate the CT reconstruction for contrast extravasation, urethral occlusion, and/or urethral narrowing.

To perform a CT cystogram, insert the Foley into the bladder, inflate the balloon, and instill 300 to 400 mL of contrast solution into the bladder. One approach is to use a gravity feed method by suspending contrast 3 to 4 feet above the patient just prior to and during imaging. An alternative is a CT of the abdomen and pelvis while obtaining complete views of the bladder.²⁴

FIGURE 176-4. Retrograde cystography. **A.** The Foley catheter is inserted into the penis. **B.** The Foley catheter is advanced until it is inside the urinary bladder. **C.** The cuff is inflated. The catheter is then pulled until resistance is met to occlude the urethra with the cuff.

FIGURE 176-5. An extraperitoneal injury. Contrast extravasation from the region of the membranous urethra to the prostatic urethra and below the bladder neck. Note the femoral fracture, pelvic fractures, and the bladder filling representing a partial urethral disruption. (Courtesy of Eric F. Reichman, PhD, MD.)

ASSESSMENT

In a normal retrograde urethrogram, the entire urethra should be visible. Some of the contrast material should also be seen within the bladder. Extravasation of contrast from the urethra will appear as a flame-like density outside the urethra (**Figure 176-5**). A partial urethral disruption will show extravasation of contrast as well as contrast within the bladder (**Figure 176-5**). An image where no contrast material is visible within the bladder is indicative of a complete urethral disruption. Contrast material may occasionally be seen in the venous plexus of the penis due to forceful injection of contrast into the urethra. **This is a common phenomenon and should not be mistaken for extravasation.** The venous flush will clear spontaneously on a postvoid film.

The evaluation of the retrograde cystogram can be performed after a plain film or CT scan (**Figure 176-6**). Intraperitoneal and extraperitoneal bladder injuries can be differentiated. **This differentiation is important because each requires a different treatment.**²⁵ Intraperitoneal bladder injuries usually result from a direct blow to the abdomen with a distended bladder.²⁶ Contrast material outlines the intraperitoneal organs with intraperitoneal bladder injuries. Extraperitoneal bladder injuries usually result from the shear forces from pelvic ring disruption due to pelvic fractures.²⁶ The extravasation of contrast material that appears as a flame-like projection confined to the pelvis constitutes an extraperitoneal injury. All intraperitoneal injuries are managed surgically whereas some extraperitoneal injuries can be managed with Foley catheter drainage (Chapter 173) or a suprapubic bladder catheter (Chapter 175).⁷

FIGURE 176-6. The cystogram. The pear-shaped bladder is elevated from the pelvic floor by a hematoma seen on CT scans. Note the femoral fracture and the pelvic fractures. (Courtesy of Eric F. Reichman, PhD, MD.)

AFTERCARE

Patients may experience burning and dysuria due to the hypertonicity of contrast material and urethral stretching. Ensure that the patient is well hydrated after a normal study. The flow of urine will wash residual contrast out of the bladder and urethra.

COMPLICATIONS

Several complications can result from retrograde urethrography and cystography. Mechanical trauma from the catheter or balloon can result in bleeding, urethral injury, bladder perforation, and conversion of a partial urethral disruption into a complete urethral disruption. Adverse reactions to contrast agents can occur.²⁷⁻³⁰ These may be due to local reactions or absorption of contrast into the blood. These reactions can range from itching and skin rashes to anaphylaxis and Stevens-Johnson syndrome. Treat any adverse reactions as any other allergic or hypersensitivity reaction.

SUMMARY

The retrograde urethrogram should be performed in any male with a pelvic fracture, lower abdominal trauma with gross hematuria, inability to void, hematoma of the perineum, or a high-riding or boggy prostate on physical examination. The cystogram should follow to evaluate potential bladder injury. The cystogram is used to evaluate and differentiate intraperitoneal versus extraperitoneal injuries.

Retrograde urethrography and cystography are diagnostic procedures that are easy to perform and have the potential to avoid major

complications related to urine leakage. Both of these procedures are safe and simple to perform. With basic equipment, invaluable information can be collected with minimal time investment. The early recognition of disruption of the lower genitourinary tract can prevent significant morbidity.

Anesthesia of the Penis, Testicle, and Epididymis

Eric F. Reichman

INTRODUCTION

A wide range of urologic procedures are performed using local or regional anesthesia. This includes an orchiectomy, inspection of the painful testis, release of a paraphimosis, dorsal slit, circumcision, and even a hydrocelectomy or varicocelectomy done in the Operating Room. Emergency Physicians can use some of the same anesthetic techniques, namely the penile or spermatic cord blocks, to safely and painlessly perform many procedures in the Emergency Department. These techniques are easy to learn, simple to perform, and have a low risk of serious complications.

ANATOMY AND PATHOPHYSIOLOGY

Innervation of the penis arises from the pudendal nerve that is derived from sacral levels 2 to 4. The pudendal nerve divides into the perineal and the inferior rectal nerves. The perineal nerve further divides into the right and left dorsal nerves of the penis. The dorsal nerves of the penis pass under the pubic symphysis to penetrate the suspensory ligament of the penis.¹ They travel under Buck's fascia to supply sensory innervation to the entire penis (**Figure 177-1**).

The primary nerve supply of the testis and epididymis is from the ilioinguinal and genitofemoral nerves. The ilioinguinal nerve is derived from the first lumbar spinal nerve. It arises slightly inferior and medial to the anterior superior iliac spine and courses

FIGURE 177-1. Transverse section through the base of the penis.

toward the pubic tubercle between the internal and external oblique muscles.^{1,2} It enters the inguinal canal on the anterior surface of the spermatic cord. The ilioinguinal nerve provides sensory innervation to the skin of the upper thigh, base of the penis, and upper scrotum.¹ It also provides sensory innervation to the spermatic cord and testicle. The genitofemoral nerve is derived from the first two lumbar spinal nerves. It divides into the genital branch and the femoral branch. The genital branch enters the inguinal canal at the external inguinal ring and travels with the spermatic cord. It provides sensory innervation to the lower scrotum, cremaster muscle, spermatic cord, and scrotum. The femoral branch supplies the skin of the anteromedial thigh.¹

INDICATIONS

Emergency Department procedures that are facilitated by local anesthesia of the penis include a dorsal slit of the foreskin, release of a phimosis or paraphimosis, repair of penile lacerations, and release of penile skin entrapped in zippers. Local anesthesia can also be used before performing a circumcision. However, this procedure is usually not performed in the Emergency Department.

The Emergency Department indications for a spermatic cord block include the relief of epididymal pain, the facilitation of a manual or ultrasound examination when differentiating between torsion and epididymitis, and to inspect the testis following trauma. Manual detorsion of a testis may be enabled by local anesthesia when a patient cannot tolerate the pain of palpation. **This should be performed only if the patient will be taken immediately to the Operating Room for confirmation of detorsion and an orchiopexy.** However, the risk of compromising the blood supply to the testis and the loss of patient assessment of pain in determining the success of detorsion are often cited as contraindications to spermatic cord blockade when testicular torsion is suspected.

CONTRAINDICATIONS

Local anesthesia is contraindicated in testicular torsion as there is a risk of compromising the testicular blood supply. The anesthetic effect will also eliminate the patient's assessment of pain that is needed to determine the success of manual detorsion. Agents containing epinephrine are not to be used in or around the penis.^{3,4} The arteries of the penis are end arteries and vasoconstriction can result in tissue ischemia and sloughing. To minimize the spread of infection, local anesthetic should not be directly injected into an area of local infection.

EQUIPMENT

- 25 and 27 gauge needles
- Syringes (3 mL, 5 mL, 10 mL)
- Povidone iodine or chlorhexidine solution
- Alcohol pads
- 4×4 gauze squares
- Local anesthetic solution without epinephrine
- Ultrasound machine
- Ultrasound linear frequency transducer, 5 to 10 MHz
- Sterile ultrasound transducer cover
- Sterile ultrasound gel
- EMLA cream

Several local anesthetic agents are commonly used for genitourinary anesthesia. These include lidocaine, bupivacaine, mepivacaine, and chlorprocaine (Table 177-1). **The anesthetic agent,**

TABLE 177-1 Local Anesthetic Agents Commonly Used for Genitourinary Anesthesia

Anesthetic agent	Strength (%)	Onset of action (minutes)	Duration of action (minutes)	Maximum dose (mg/kg)
Lidocaine	0.5, 1.0, 1.5, 2.0	5–15	45–90	4.5
Bupivacaine	0.25, 0.50	10–15	120–240	2.5
Mepivacaine	1.0, 1.5	10–15	120–240	4.0
Chlorprocaine	2.0, 3.0	10–15	20–40	11.0

concentration, and technique must be chosen so that the maximum safe dose is not exceeded. This is especially important when performing anesthesia in children.

The use of a local anesthetic agent containing epinephrine will prolong the block and give the patient a longer interval of pain-free time. However, the use of epinephrine is controversial. Epinephrine-containing local anesthetics can cause penile vasoconstriction and ischemia.^{4,5} There are also reports of penile ischemia with local anesthetics not containing epinephrine.^{6,7} Recently there was research stating epinephrine-containing local anesthetics in penile surgery are safe.⁸ There is not enough information on the safety of epinephrine-containing local anesthetics on the penis. The safest recommendation is not to use epinephrine-containing local anesthetics on the penis as most Emergency Department procedures on the penis are short.

There are several alternative techniques that can be used. EMLA cream has been used in office procedures similar to the ones performed in the Emergency Department.⁹ EMLA cream provided almost all participants excellent anesthesia. The only downside of using EMLA is the time it takes for the anesthesia to take effect. Acupuncture on bilateral forearm points prior to the penile block eased the pain when performing the block.¹⁰ The use of acupuncture is outside the training of Emergency Medicine and not used in US Emergency Departments.

PATIENT PREPARATION

The patient and/or their representative must be informed of the procedure including its risks and benefits. The explanation must include the risks of local anesthetic injection and the possibility that the anesthetic may not effectively eliminate pain. The risks associated with the injection include pain, hematoma formation, and bleeding. Infection is a late risk that can be reduced by prepping the skin and using sterile technique. Obtain an informed consent for the anesthetic procedure in addition to the consent for the procedure that will be performed under anesthesia.

The patient's ability to cooperate with the planned procedures must be assessed. Consider oral or parenteral sedation, especially in anxious patients or children. Midazolam (0.02 to 0.04 mg/kg intravenously [IV]) or diazepam (2.5 to 5 mg IV) is often a good choice in adults. Children may benefit from midazolam parenterally (0.05 to 0.15 mg/kg IV) or orally (0.5 to 0.7 mg/kg). Ketamine (1.0 to 1.5 mg/kg IV or 2 to 5 mg/kg intramuscularly) with or without atropine (0.01 mg/kg) to reduce respiratory secretions is an alternative, especially in children younger than 10.

Clean any dirt and debris from the skin. Identify the anatomic landmarks required to perform the anesthetic injection. Apply povidone iodine or chlorhexidine solution to the area where the anesthetic is to be injected. The povidone iodine or chlorhexidine may also be applied to the penis and scrotum if an invasive procedure is subsequently to be performed. Apply sterile drapes to delineate a surgical field. Allow the povidone iodine or chlorhexidine to dry.

Put on sterile gloves and reidentify the anatomic landmarks. Infiltrate with local anesthetic solution using sterile technique.

TECHNIQUES

LOCAL INFILTRATION

Local anesthetic infiltration of the skin of the penis is useful for the repair of superficial lacerations, dorsal slits of the foreskin, or freeing entrapped skin from a zipper. Local infiltration circumferentially around the penis will provide adequate anesthesia distal to the anesthetic injection site.¹¹ The circumferential subcutaneous injections can be performed directly on the penis or on the abdominal wall and scrotum surrounding the penis. While not contraindicated, some authors avoid direct infiltration of the foreskin as tissue sloughing may result.² **Local infiltration of anesthetic agents is often extremely painful for the patient. Consider premedicating the patient with parenteral benzodiazepines and/or narcotic agents.**

Local anesthetic agents can be injected subcutaneously into the penis to provide distal anesthesia. If performing a dorsal slit of the foreskin, raise a skin wheal of local anesthetic solution at the base of the foreskin in the 12 o'clock position (**Figure 177-2A**). Insert the needle through the skin wheal aimed distally. Inject local anesthetic solution subcutaneously as the needle is advanced to the distal edge of the foreskin. Alternatively, local anesthetic solution can be circumferentially infiltrated around the penis (**Figure 177-2B**). This block usually requires 6 to 10 mL of local anesthetic solution in the adolescent or adult and 2 to 3 mL in a child.

PENILE BLOCK

The objective of a penile block is to anesthetize the right and left dorsal nerves of the penis that provide sensation to the penis (**Figure 177-1**). **The dorsal nerves should be blocked as close to the base of the penis as possible. If the block is performed too distal to the pubic bone, the posterior branches of the dorsal nerves will not be anesthetized and the ventral surface of the penis will retain sensation.**¹¹⁻¹³ Multiple effective techniques will be described to perform a penile block. The technique chosen should depend on

FIGURE 177-2. Local anesthetic infiltration into the penis. **A.** A skin wheal is raised and local anesthetic is injected distally (dotted line). **B.** Circumferential infiltration of local anesthetic solution.

FIGURE 177-3. Local anesthetic infiltration around the base of the penis. The dots represent the locations of the skin wheals.

the specific procedure to be performed, the level of patient cooperation, and the preference of the Emergency Physician.

The penis may be anesthetized where it forms along the abdominal wall.² This block anesthetizes the nerves to the penis before they reach the penis. Place three skin wheals using local anesthetic solution on the abdominal and scrotal skin, 0.5 to 1.0 cm from the base of the penis, at the 2 o'clock, 6 o'clock, and 10 o'clock positions (**Figure 177-3**). Infiltrate subcutaneously with local anesthetic solution between the skin wheals to form a triangle of anesthetic that surrounds the base of the penis. This block usually requires 8 to 12 mL of local anesthetic solution in the adolescent or adult and 3 to 5 mL in a child.

The dorsal nerves of the penis can be anesthetized as they course onto the penis. Place a skin wheal of local anesthetic solution at the 2 o'clock and 10 o'clock positions.^{14,15} Slowly insert a 27 gauge needle through the skin wheals until there is a slight loss of resistance indicating penetration of Buck's fascia (**Figure 177-4**). Aspirate to ensure that the needle is not within a blood vessel. Inject 2 mL of local anesthetic solution at each site in the adolescent or adult and 0.3 to 0.5 mL in a child.¹

Another technique blocks the dorsal nerves as they pass through the triangular space bordered by the pubic symphysis, the corpora cavernosa, and Buck's fascia. Place a skin wheal of local anesthetic solution at the dorsal base of the penis. Insert the needle through the skin wheal and to the pubic symphysis. Withdraw the needle slightly and advance it caudally until a loss of resistance is felt indicating it has penetrated Buck's fascia. Aspirate to ensure that the needle is not within a blood vessel. Inject 10 mL of local anesthetic solution on each side of the suspensory ligament (midline) in the adolescent or adult and 2 to 3 mL in a child. Alternatively, the same block can be accomplished with a separate injection on each side of the midline.^{1,16}

ULTRASOUND-GUIDED PENILE BLOCK

Ultrasound has been successfully used in the dorsal penile block.¹⁷⁻²⁰ Ultrasound allows real-time visualization of local anesthetic injection and spread, decreases inadvertent injection into the corpora

FIGURE 177-4. The penile block anesthetizes the left and right deep dorsal nerves of the penis.

cavernosa, decreases the risk of vascular injection, decreases volume of local anesthetic used, and increases success rates. The traditional blind or landmark technique does not always work due to injection of the local anesthetic above Buck's fascia, intracorporeally, or intravascularly. One study showed there was no difference in the ultrasound versus the landmark technique.¹⁸

Use a linear transducer in the 5 to 10 MHz range. Identify with ultrasound Buck's fascia, the dorsal penile nerves, and the dorsal penile vasculature (**Figure 177-5**). Clean and prep the penile skin.

FIGURE 177-5. Artist illustration of the ultrasound-guided penile block. (Photo courtesy of M-I Suleman, from *Anesthesia News* 2015; 41(5):10-13.)

FIGURE 177-6. Ultrasound of the penis. DA, dorsal artery; DV, dorsal vein; DPN, dorsal penile nerve; BF, Buck's fascia; CC, corpus cavernosum; CS, corpus spongiosum. (Photo courtesy of M-I Suleman, from *Anesthesia News* 2015; 41(5):10-13.)

Prepare the transducer using sterile ultrasound gel and a sterile cover. Repeat the ultrasound, sterilely, to identify the structures (**Figure 177-6**). Use the in-plane approach. Inject the 2 to 4 mL of the local anesthetic agent at the 1 o'clock position (**Figure 177-7A**). Watch the ultrasound machine screen to confirm the injection and spread of local anesthetic solution under Buck's fascia (**Figure 177-7B**). This technique allows one injection to anesthetize the penis.

SPERMATIC CORD BLOCK

As the spermatic cord exits the external inguinal ring, it passes over the pubic tubercle and continues medially toward the scrotum. In this same location, the ilioinguinal nerve travels on the anterior surface of the spermatic cord and the genital branch of the genitofemoral

A

nerve on the posterior surface. These two nerves supply sensation to the spermatic cord, epididymis, and testicle. Anesthesia of the spermatic cord in the region of the pubic tubercle will provide anesthesia to the testis and its covering, the epididymis, and the vas deferens.¹³ **The spermatic cord block does not provide anesthesia to the skin of the scrotum.** Additional subcutaneous infiltration is necessary for an incision of the scrotal skin.

This first spermatic cord block technique is useful in thin patients with a palpable pubic tubercle. Identify the pubic tubercle by palpation. Inject local anesthetic solution to make a skin wheal just medial and 1 cm below the pubic tubercle (**Figure 177-8**). Gently advance a 25 gauge needle laterally through the skin wheal and spermatic cord until bone is contacted. Aspirate to ensure that the needle is not within a blood vessel. Inject 3 to 4 mL of local anesthetic solution as the needle is slowly withdrawn in the adolescent or adult and 1 to 2 mL in a child. Repeat the procedure two more times using the same skin puncture site, each time passing through the cord at a slightly different angle. This block requires a total of 10 to 12 mL of local anesthetic solution in the adolescent or adult and 3 to 5 mL in a child.¹³

FIGURE 177-8. The spermatic cord can be anesthetized just below the pubic tubercle if the tubercle is palpable. The arrows represent the three different directions required to inject local anesthetic solution.

A modified technique is used for the patient in whom the pubic tubercle is difficult to palpate. Grasp the spermatic cord between the nondominant thumb and index finger as it enters the scrotum (**Figure 177-9**). Place a wheal of local anesthetic solution between the fingers and above the spermatic cord. Insert a 25 gauge needle through the skin wheal. Direct the needle anterior to the spermatic cord. Aspirate to ensure that the needle is not within a blood vessel. Inject 3 to 4 mL of local anesthetic solution in the adolescent or adult and 1 to 2 mL in a child. Repeat the process on the medial and lateral side of the spermatic cord.

FIGURE 177-9. The spermatic cord block at the base of the scrotum. Local anesthetic solution is injected anteriorly (1), laterally (2), and medially (3) to the spermatic cord.

Alternatively, palpate the spermatic cord as it enters the scrotum.²¹ Trace the spermatic cord superiorly to the pubic tubercle where it exits the external inguinal ring. Trap the spermatic cord between the second and third fingers of the nondominant hand and the pubic tubercle. Place a wheal of local anesthetic solution between the fingers and above the spermatic cord. Insert a 25 gauge needle through the skin wheal. Aspirate to ensure that the needle is not within a blood vessel. Inject local anesthetic solution anteriorly, medially, and laterally to the spermatic cord as described above. Injection of local anesthetic solution around the spermatic cord as it exits the inguinal canal may be less painful than injection as it enters the scrotum.

ASSESSMENT

Allow 10 to 15 minutes for the local anesthetic solution to take effect for a penile block. Test the level of anesthesia by pinching the skin with a forceps or by pinprick with a needle. The patient may feel a pressure sensation but should not feel pain. If the test stimulus is painful, repeat the block or use additional anesthetic techniques prior to performing the procedure.

Spermatic cord blocks require 10 to 15 minutes for maximal effectiveness. The patient should be warned that, despite an effective block, traction on the spermatic cord might cause nausea and a tugging sensation. These will resolve upon release of the traction.¹³ Additional anesthesia must be applied to the scrotal skin for any incisions or procedures as a spermatic cord block does not anesthetize the scrotal skin.

AFTERCARE

Minimal aftercare is required for these local anesthetic techniques. Depending on the agent used, sensation may return in as little as 1 to 2 hours (e.g., lidocaine, chloroprocaine) or up to 4 hours (e.g., bupivacaine). The skin may awaken with a pins-and-needles sensation. Patients should use caution when zipping their pants so as not to catch the penis, foreskin, or scrotum as they will not feel the injury. Patients should be warned that the site of a spermatic cord block might remain tender for as long as 10 days.¹³ The application of cool compresses to the injection site and oral nonsteroidal anti-inflammatory drugs will provide adequate analgesia for the injection site pain. Patients should inspect the injection site and surrounding area three to four times a day for any signs of infection. They should return to the Emergency Department immediately if any problems or concerns arise.

COMPLICATIONS

The most procedure-specific complication of a penile block is sloughing of the penile skin. This is more common in the region of the glans. Performing the penile block at the base of the penis and using solutions without epinephrine minimize this risk.

Hematomas can be quite large in spermatic cord blocks because the venous plexus is usually pierced. The use of a smaller needle and careful application of pressure can help prevent hematomas. Blood loss from puncturing a vascular structure is easily controlled with direct pressure. A Urologist should be consulted urgently in the rare occasion that bleeding does not resolve with pressure. Most hematomas will resolve within 1 to 2 weeks. The application of warm compresses to the hematoma several times a day may result in quicker resorption.

Local infection at the injection site is possible. Patients should be warned about the signs of infection including fever, erythema, warmth, induration, increased pain, and purulent drainage. Patients should seek immediate medical attention for any of these symptoms.

The injection of local anesthetic can cause inflammation in the short term.²² It should not be confused with an infection.

Toxic levels of anesthetic agents can affect multiple organ systems, most notably the central nervous and cardiovascular systems. Anesthetic agents block the inhibitory neurons of the brain producing a state of neuro-excitation. Initial symptoms may include tinnitus, premolar numbness, disorientation, lightheadedness, or nystagmus. This may progress to seizures that can be accompanied by slow or absent breathing, acidosis, aspiration, and cardiovascular instability. Intravenous diazepam (2.5 to 5 mg) at the first sign of symptoms may stop the cascade.² Significantly higher doses of diazepam are required to treat local anesthetic-induced seizures. Very high levels of local anesthetics are cardiotoxic and may result in a heart block. Heart block from bupivacaine toxicity is associated with resistance to resuscitative maneuvers. The onset of all local anesthetic toxicities is faster with intravascular injection versus toxic tissue concentrations. Consider the use of intravenous lipid emulsion (Chapter 153) for any local anesthetic toxicity.

SUMMARY

Local anesthesia allows many painful genitourinary procedures to be performed in the Emergency Department. The techniques are simple and easy to perform with little to no experience. Local anesthetic solutions containing epinephrine should never be used to anesthetize the penis, scrotum, or spermatic cord.

Priapism Management

Steven Go

INTRODUCTION

Priapism was first described in the English literature in an 1824 case report by Callaway.^{1,2} **Priapism is defined as a prolonged engorgement or erection of the penis or clitoris that lasts over 4 hours, occurs beyond sexual stimulation or arousal, or occurs apart from sexual stimulation or arousal.**³ The term “priapism” derives its origin from the name of a minor Greek god of fertility and growth named Priapus.⁴ He was prenatally cursed by Hera with “out of proportion genitals, ugliness, lewdness, and impotence.” A famous Pompeiian fresco graphically illustrates Priapus’ plight as he weighs his massive phallus with a hanging scale.⁴ His humiliated and demoralized demeanor in ancient mythology seems to parallel that of many present-day afflicted patients.⁵

Priapism affects an estimated 5.34 cases per 100,000 person-years in the general US male population.⁶ It was present in 2.3% of Emergency Department visits by male sickle cell patients from 2006 to 2010.⁷ There is a predilection for presentation during the summer months.⁶ The most common form of priapism is often excruciatingly painful and is frequently embarrassing to the patient. This can result in delays seeking medical attention. Priapism can sometimes lead to permanent erectile dysfunction without swift and expert intervention.

Priapism is classified into the major subtypes of ischemic, non-ischemic, and stuttering priapism (Table 178-1).⁸⁻¹¹ Stuttering priapism is often associated with sickle cell anemia. It is critical that

TABLE 178-1 The Clinical, Penile Blood Characteristics, and Color Doppler Flow Differences Between Ischemic and Nonischemic Priapism

	Ischemic priapism	Nonischemic priapism
Clinical characteristics	Pulsations Rigid penis Usually atraumatic Very painful	Less tense penis Minimal pain No pulsations Often traumatic
Penile blood characteristics	Dark appearance PaCO ₂ > 60 mmHg PaO ₂ < 30 mmHg pH < 7.25 Thick consistency	Bright red appearance PaCO ₂ < 60 mmHg PaO ₂ > 30 mmHg pH > 7.25 Thin consistency
Color Doppler flow pattern	Low arterial inflow Low/no venous outflow	High arterial inflow Venous outflow

TABLE 178-2 Some Etiologies of Ischemic Priapism

Drug-induced	Idiopathic
α-Blockers	Most common etiology
Androgens	Occurs in 21%–33%
Anticoagulants	Malignancies
Antidepressants	Metastatic cancer
Antihypertensives	Primary penile cancer
Antipsychotics	Miscellaneous
Anxiolytics	Amyloidosis
Cocaine	Black widow spider bites
Crack cocaine	Carbon monoxide
Erectile dysfunction agents	Dialysis
Ethanol	Fabry disease
Gonadotropin-releasing hormone	G6PD deficiency
Hormones	Genitourinary trauma
Impotence agents orally	Gout
Marijuana	Herbal supplements
PDE5 inhibitors (e.g., sildenafil)	Hypertriglyceridemia
Prostaglandins	Malaria
Sympathomimetics	Rabies
Testosterone	Scorpion stings
Hematologic disorders	Total parenteral nutrition
Factor V Leiden	Neurologic
Fat emboli associated with total parenteral nutrition	Autonomic neuropathy
Leukemia	Cauda equina syndrome
Myeloma	Lumbar disk herniation
Polycythemia	Medullary injury
Sickle cell disease	Spinal anesthesia
Thalassemia	Spinal cord lesions
Iatrogenic	Spinal stenosis
Intracavernous erectile therapy	Stroke
Surgery	Syphilis

Source: References 10, 23, 25–43.

the Emergency Physician determines which subtype the patient has because emergent management and prognosis differ considerably.

The presenting subtype is ischemic (i.e., low flow or vaso-occlusive) in 95% of priapism cases and poses the greatest risk of permanent penile dysfunction. This type of priapism is of the greatest concern to the Emergency Physician. It is generally thought to result from an impediment to blood emptying from the penis regardless of the etiology (Table 178-2).

The patient presents with a very painful rigid penis with engorgement of both corpora cavernosa (Table 178-1). The corpus spongiosum and the glans are usually spared, although they can be involved in rare instances.¹² This situation forms a type of compartment syndrome if left untreated. It can result in fibrosis, loss of function, scarring, and penile gangrene in extreme cases. Priapism outcomes are often dismal. Reported rates of complete erectile dysfunction occur in > 35% of patients with treatment and to up to 90% without treatment.^{13,14}

The second main subtype of priapism is nonischemic (i.e., high flow or arterial) and is far less common than ischemic priapism (Table 178-1). It is caused by excess penile arterial blood flow that is often secondary to perineal or penile trauma (e.g., including iatrogenic or postprocedure).^{15,16} Patients present with a painless partially erect penis. Arterial blood is freely flowing through the penis and the outcomes of nonischemic priapism tend to be more favorable than those of ischemic priapism, although subsequent erectile dysfunction can occur.¹⁷ The Emergency Department management is generally supportive and requires no procedural intervention in most cases.

Stuttering or intermittent ischemic priapism is a variant of ischemic priapism in which the patient suffers intermittent priapism episodes over time. This variant is most frequently seen in sickle cell disease patients. Stuttering priapism episodes may become prolonged (i.e., > 4 hours) and are treated in the same fashion as ischemic priapism.

ANATOMY AND PATHOPHYSIOLOGY

RELEVANT ANATOMY

The penis is primarily composed of the dual dorsal corpora cavernosa and a single ventral corpus spongiosum (**Figure 178-1**). The corpora cavernosa surrounds the cavernous and the helicine arteries. The corpora cavernosa are the structures engorged during most cases of priapism. The corpus spongiosum surrounds the urethra and forms the glans. A superficial and deep neurovascular bundle is located on the dorsal surface of the penis.

The corpora of the penis consist of spongy networks of collagen, endothelial tissue, nerves, smooth muscle, and vascular structures. The primary arterial supply to the penis arises from the internal pudendal artery which gives rise to the cavernous artery and supplies the lacunar spaces in the corpora cavernosa. Another two branches of the internal pudendal artery, the bulbourethral and dorsal arteries, supply blood to the corpus spongiosum and glans. The cavernous artery dilates during an erection and blood flows through the helicine arteries into the sinusoidal spaces of the corpora cavernosa causing them to expand. The corpora cavernosa swell against a strong fibrotic outer layer (i.e., tunica albuginea) which produces a rigid penis.¹⁸ **An important functional anatomic feature is that blood flows freely between both corpora cavernosa through the incomplete septum between them.**

Venous outflow regulation plays an equally important role in maintaining an erection.¹⁹ The venous drainage is complex with paired branches running with the arteries. An additional major drainage system enters the deep dorsal vein via the multiple emissary veins and circumflex veins. The extensive subtunical plexus of veins feeds into the emissary veins that perforate the tunica albuginea and drain into the circumflex veins. The increasing distention of the corpora cavernosa during an erection with arterial blood causes the compression of the subtunical venous plexus. Stretching of the tunica albuginea obstructs drainage through the emissary veins and restricts venous outflow further. There is no venous outflow obstruction to the glans and corpus spongiosum until the rigid-erection phase. The glans and corpus spongiosum do not typically develop the higher pressure of the corpora cavernosa.

NORMAL ERECTION PHYSIOLOGY

An erection begins when the parasympathetic nervous system activates the nitric oxide (NO)-cyclic guanosine monophosphate (cGMP) pathway.²⁰ This begins a cascade of neurotransmitter events involving adenosine.²¹ It culminates in decreased intracellular calcium from smooth muscle cells. The erection is the result of relaxation of the smooth muscle in the arterial walls and the corpora cavernosa. The primary mechanism of detumescence is mediated through the cGMP-specific type 5 phosphodiesterase (PDE5) enzyme which helps bring about contraction of smooth muscle.²² This reduces arterial inflow and reduces corpora cavernosa volume which serves to promote venous outflow resulting in penile flaccidity.

ISCHEMIC PRIAPISM PATHOPHYSIOLOGY

There have been many recent advances in the understanding of the molecular mechanisms of ischemic priapism.^{20,23} Chief among

FIGURE 178-1. Cross-section of the penis demonstrating the anatomy.

these is the dysregulation of the NO-cGMP signaling pathway that results in an exaggerated erectile response in the smooth muscle.²² The chronic decrease in NO causes reduced levels of PDE5 further hampering penile relaxation. Other defects in the RhoA/Rho kinase (ROCK) vasoconstrictor pathway, excessive adenosine signaling, increases in opiorphin levels, and oxidative-nitrosative stress have all been implicated in ischemic priapism.²²

NONISCHEMIC PRIAPISM PATHOPHYSIOLOGY

Nonischemic priapism generally results from a trauma-induced arteriovenous communication between the cavernous artery and the sinusoidal spaces bypassing the high resistance helicine arteries. This results in unrestrained arterial flow. The penis is not at risk for ischemia because there is no increased venous constriction limiting outflow.

STUTTERING PRIAPISM PATHOPHYSIOLOGY

The mechanisms of stuttering priapism overlap with those of ischemic priapism. It includes additional mechanisms from the sickling erythrocytes in sickle cell disease patients (e.g., venous stasis and congestion).²⁴

INDICATIONS

DETERMINING THE PRIAPISM SUBTYPE

The initial evaluation by the Emergency Physician must be accurate, aggressive, and quick. The key diagnostic decision to be made in a patient presenting with priapism is to determine whether it is ischemic or nonischemic.¹⁰ This distinction is important. Delays in

emergent therapy increase the chance of poor outcomes in ischemic priapism whereas nonischemic priapism usually only requires supportive care and close follow-up with a Urologist. There are several differences in the presentation of ischemic and nonischemic priapism that allow the Emergency Physician to tell these subtypes apart (Table 178-1). Some of the etiologies of ischemic priapism are listed in Table 178-2.^{10,23,25-43}

The clinical features that characterize ischemic priapism can generally be detected with a careful history and physical examination. It is recommended to confirm clinical impression on every priapism patient by sampling the penile blood for arterial blood gas analysis or by a color Doppler ultrasound (Figures 178-2 and 178-3). Penile blood can be readily sampled at the same time therapy is initiated. The sampling is somewhat invasive and can be painful. Color Doppler ultrasound is less invasive but can delay definitive therapy if it is not readily available. The choice of confirmatory test must be driven by the clinical situation and setting.

Some have recommended additional diagnostic tests in patients who present with priapism.^{3,13} This includes a complete blood count (CBC) with a manual differential to diagnose blood dyscrasias, a urinalysis as an infection screen, and various drug screens if indicated. Do not delay seeking the definitive diagnosis and treatment of ischemic priapism to obtain ancillary studies.

CONTRAINDICATIONS

The patient must be stabilized prior to dealing with the priapism if they have trauma-induced priapism and serious life-threatening injuries. Medical risks making priapism therapy inappropriate will occasionally occur and must be weighed against the fact that the natural course of priapism does not cause mortality. Do not administer

FIGURE 178-2. Transverse Doppler ultrasound image of the penile shaft in ischemic priapism. **A.** The corpora cavernosa (CC) have no flow, whereas the corpus spongiosum (CS) has some flow preserved. **B.** Close-up of the penile shaft showing flow to the tunica albuginea but not the corpora. FIGURE 178-2. (Continued)

α -adrenergic agonists in patients with dysrhythmias, significant hypertension, unstable angina, and other high-risk cardiac conditions. They are also contraindicated if the patient is taking ergotamines (except ergoloid mesylates and nicergoline), linezolid, or

monoamine oxidase inhibitors. Use α -adrenergic agonists with care in patients taking sympathomimetic drugs of abuse (e.g., cocaine). Penile aspiration, irrigation, and intracavernous injections are not efficacious in nonischemic priapism.

EQUIPMENT

- 19 gauge butterfly needle
- 21 gauge butterfly needle
- Arterial blood gas syringe
- Syringes, various sizes
- Povidone iodine or chlorhexidine solution
- 4×4 gauze squares
- Sterile drapes
- Sterile basin
- Three-way stopcock (optional)
- Phenylephrine, diluted as noted below⁴⁴⁻⁴⁶
- Local anesthetic without epinephrine
- Sterile normal saline, 1 L bottle
- Sterile normal saline, 10 mL vial
- Intravenous (IV) access supplies (Chapter 61)
- Blood pressure monitoring equipment
- Cardiac monitoring equipment
- Pulse oximeter
- Oxygen source and nasal tubing
- Sterile gloves
- Ultrasound machine, optional
- Ultrasound gel, optional
- Ultrasound transducer, optional

PATIENT PREPARATION

Obtain an emergency Urologist consult immediately when the presence of ischemic priapism is determined. Perform the procedure if a Urologist is not readily available or if the Emergency Physician is comfortable performing the procedure. Explain the risks, benefits, and alternative procedures to the patient and/or their representative. The discussion should include being transferred to a facility with a Urologist if one is not immediately available. **Informed consent is crucial in the treatment of ischemic priapism because the outcomes can be poor even with appropriate treatment.** Allow time for questions so that the patient can make an

informed and voluntary decision. Document the patient's capacity to consent, benefits, risks, alternatives discussed, and the medical decision making in the chart and obtain a signed consent form.

Obtain IV access for pain control. Place the patient on the cardiac monitor, noninvasive blood pressure cuff, pulse oximetry, and supplemental oxygen to monitor them during and after the procedure as an added level of precaution. Some adverse events have been reported during the procedures described below. This is especially true in patients with a history of cardiac dysfunction, coronary artery disease, or hypertension. Administer IV hydration and oxygen to sickle cell disease patients.

Perform ultrasonography of the penis if is available at the bedside in a reasonable amount of time. View the corpora cavernosa and vasculature of the penis. Use the normal gray scale and color Doppler (**Figures 178-2 and 178-3**). Power Doppler can be used to confirm the lack of flow to the corpora cavernosa.

Place the patient supine with their legs spread apart. Consider the administration of parenteral analgesics, sedatives, and/or conscious sedation (Chapter 159) as appropriate because these procedures can be very painful. Gently clean the penis, scrotum, and surrounding area of any dirt and debris. Apply povidone iodine or chlorhexidine solution to the penis and surrounding area and allow it to dry. Apply sterile drapes to delineate a sterile field. Perform a dorsal penile nerve block or a circumferential penile block (Chapter 177).

TECHNIQUES

PENILE ASPIRATION

Attach a blood gas syringe to the tubing of a nonheparinized 19 gauge butterfly needle. While gently applying negative pressure via the syringe, insert the needle into the lateral aspect of one of the corpus cavernosa in the midshaft of the penis and perpendicular to the shaft (**Figure 178-4**). **Insert the needle at the 3 o'clock or 9 o'clock position to avoid the neurovascular structures between 10 and 2 o'clock.** Insert the needle just far enough to freely aspirate blood. Hold the needle still so it does not move. Remove the syringe. Send the aspirated blood for blood gas analysis. Attach an additional 10 or 20 mL syringe and aspirate enough blood to significantly soften the penis (usually about 5 mL) if color Doppler ultrasound has confirmed ischemic priapism or if the blood is dark. Both cavernosa

A

B

FIGURE 178-4. The technique of penile aspiration. **A.** Artist illustration. **B.** Clinical photo. (Used with permission from Knoop KJ, Stack LB, Storrow AB, Thurman RJ (eds): *The Atlas of Emergency Medicine*, 4th ed. New York: McGraw-Hill; 2016. Photo contributor: David Effron, MD.)

may be decompressed through the single drainage needle since the cavernosa communicate across the incomplete septum. Continue drainage until fresh red oxygenated blood is aspirated.⁸ Penile blood aspiration alone is effective in inducing detumescence in approximately 30% of cases.¹³

PENILE IRRIGATION

Irrigation is appropriate if there is difficulty with the aspiration or if the priapism does not resolve with aspiration. Aspirate as described above. Carefully remove the syringe while leaving the needle in place. Insert a 19 or 21 gauge butterfly needle (i.e., the second needle) into the corpora in the proximal shaft area (**Figure 178-5**). **Insert the needle at the 3 o'clock or 9 o'clock position to avoid the neurovascular structures between 10 and 2 o'clock.** Begin gentle irrigation with normal saline through the second butterfly needle with outflow through the first butterfly needle (**Figure 178-5**). This will

help to irrigate out the old, dark blood. **Use only normal saline to prevent damage to the endothelium if the solution is not isotonic.** Massaging the penis to “milk out” sludge can be helpful. Placement of additional 19 gauge butterfly needles may be used to improve drainage in difficult cases. **The fewer the injections administered, the less chance for forming a hematoma.**

INTRACAVERNOUS SYMPATHOMIMETIC INJECTION

Intracavernous injection is recommended if aspiration and irrigation fail to resolve the priapism. Phenylephrine is the agent of choice.^{8,13,44-46} **Systemic sympathomimetic side effects may occur. Monitor the patient's vital signs and cardiac rhythm during the injection. Use great caution and lower dosages in vasculopathic patients and be prepared to deal with potential cardiovascular complications.** Many medications have been used to relieve

FIGURE 178-5. The irrigation of the corpora cavernosa. (Used with permission from reference 10.)

TABLE 178-3 The Medications Used to Treat Ischemic Priapism**Intracavernous injection**

Epinephrine, 0.03–0.05 mg
 Etylephrine, 2–20 mg
 Methylene blue, 50 mg
 Norepinephrine, 0.01–0.02 mg
 Phenylephrine, 0.1–1.0 mg

Intramuscular injection

Ketamine, 1 mg/kg

Intravenous injection

Dopamine, 2–4 µg/kg
 Ketamine, 1 mg/kg

Oral Administration

Pseudoephedrine, 0.5 mg/kg to maximum 30 mg does
 Terbutaline sulfate, 5 mg

priapism (**Table 178-3**). The most experience in the Emergency Department is with phenylephrine. Deaths have been reported with agents other than phenylephrine. The use of phenylephrine rarely has been reported to give rise to serious complications and is the agent of choice.^{44–46} Save the other medications for the Urologist.

Mix 10 mg of phenylephrine with 9 mL of sterile normal saline to produce a concentration of 1 mg/mL (i.e., 1000 µg/mL). Fill a tuberculosis syringe with the diluted solution through the butterfly catheter and into the penis. Observe the penis every 3 to 5 minutes and repeat the procedure if the erection returns or does not resolve. There is no definite limit to the cumulative amount of phenylephrine used for injections. Current recommendations are to not conclude that intracavernous injections have failed until the patient has been treated for 1 hour or with a total of 1 mg of phenylephrine.^{8,13} **Discontinue the injection immediately if untoward cardiovascular side effects occur.**^{44–46}

α_1 -Adrenergic receptors are less able to cause smooth muscle contraction in longer episodes of priapism. Intracavernous injection therapy becomes less likely to succeed over time. Higher doses of up to 50,000 µg have been suggested in long-standing episodes of priapism.⁴⁷

PEDIATRIC CONSIDERATIONS

The telling of others of the prolonged erection can be embarrassing. The treatment of ischemic priapism can emotionally and psychologically traumatize the pediatric patient. Use sensitivity toward the patient and their caregivers. Explain any treatment and allow questions. Aspiration and irrigation of the corpora cavernosa are the same as in an adult. Use 1 µg/mL of epinephrine for the intracavernosal injection if the patient is below the age of 11 years.

AFTERCARE

Remove the needle(s) and compress the puncture site for 30 to 60 seconds every time a needle is withdrawn from the penis to avoid a hematoma. The penis should resume a soft state after treatment. Reassess the penis with color Doppler ultrasound or repeat the penile blood gas assessment if it is not clear that treatment has been effective.³ Absence of arterial blood in-flow on ultrasound or penile blood acidosis suggests treatment failure. Consider alkalinization and exchange transfusion in sickle cell disease patients. An emergent surgical procedure by a Urologist (i.e., venous shunting) is indicated if aspiration, irrigation, and injection fail.¹⁰

Observe the patient for at least 30 minutes before assuming successful detumescence. **Do not apply a compression dressing to the penis.** There are no randomized controlled data to support the

use of prophylactic antibiotics after aspiration, irrigation, and/or intracavernous therapy and they are not recommended in current guidelines.^{8,13} Referral to an appropriate specialist depends on the cause of the priapism. Treat the offending mechanism or discontinue the medication if an underlying condition or medication is a suspected cause. Make the appropriate disposition and follow-up. **Follow-up with a Urologist within 24 hours is necessary in all patients. Document a detailed procedure note because of the legal risk involving priapism and its treatment. Give the patient written instructions and document these instructions in the medical record.**

COMPLICATIONS

The butterfly needle may lacerate the cavernous artery during aspiration which will be evidenced by the presence of pulsatile arterial blood. Emergent evaluation by a Urologist is indicated if such an injury is suspected. The long-term sequelae to unresolved priapism are fibrosis of the corporal tissue and loss of erectile function. Erectile dysfunction may still occur in patients despite successful detumescence. Varying degrees of fibrosis may be found on physical examination at a later date. Treatment by aspiration and irrigation can be associated with hematoma formation, infection, urethral injury, or vascular injury. The use of α -adrenergic agonists can have the systemic effects of flushing, headache, hypertension, reflex bradycardia, tachycardia, and other dysrhythmias. Deaths have been reported with agents other than phenylephrine. The use of phenylephrine rarely has been reported to give rise to serious complications and is the agent of choice.^{44–46}

The patient needs to be fully informed of the long-term risk of sexual dysfunction even if detumescence is successful. Recurrence of the priapism is common. Warn the patient to seek immediate care if a recurrence occurs.

SUMMARY

Priapism is an uncommon but a vexing complaint in the Emergency Department. The two major subtypes of priapism are ischemic (i.e., low flow) and nonischemic (i.e., high flow). The key decision for the Emergency Physician is to determine what type of priapism is presenting. Ischemic priapism requires prompt treatment to reduce the possibility of permanent damage to the penile tissue and subsequent erectile dysfunction. It is imperative to confirm the diagnosis with either color Doppler flow ultrasound or penile aspiration. An emergent Urologist evaluation is indicated if ischemic priapism is strongly suspected or confirmed. Perform treatment in a stepwise fashion beginning with penile aspiration followed by irrigation.²³ Attempt intracavernous injection with phenylephrine if no contraindications exist. A Urologist should perform more invasive surgical procedures if these bedside strategies fail. It is imperative that the patient be fully informed and sign an informed consent given that the incidence of erectile dysfunction following low-flow priapism is high even with treatment.

Paraphimosis Reduction

Matthew D. Schwartz and Ann P. Nguyen

INTRODUCTION

A paraphimosis is defined as the inability to reduce a proximally positioned foreskin over the glans penis and back to its normal anatomic position.¹ The most common cause for a paraphimosis is iatrogenic. Medical personnel may forget to reduce the foreskin over the glans following examination or instrumentation of the penis. This is particularly true in patients who are sedated, confused, demented, or delirious.

Elderly patients are particularly at risk as their predisposition to erectile dysfunction and decreased libido result in fewer erections to naturally dilate the foreskin. The elderly, demented, and cognitively delayed are at increased risk for poor genital hygiene and a paraphimosis.² Other patients may fail to reduce their foreskin after intercourse or urination.³ Infants and toddlers have a normal physiologic phimosis that resolves by the age of 3 in over 90% of cases. This predisposes them to a paraphimosis when well-meaning caregivers forcibly retract the foreskin during cleaning. A paraphimosis may also occur when a narrowed or phimotic foreskin is retracted and unable to be reduced. Paraphimosis has been reported secondary to genital piercing, erotic dancing, and various cutaneous lesions (e.g., hemangioma and cutaneous lymphoproliferative disorders).⁴⁻⁶

A patient with a paraphimosis usually presents with severe penile pain. The process may have a more indolent presentation in persons with impaired pain sensation (e.g., the elderly or diabetics). Patients with altered mental status may simply present with agitation and are at risk for complications of a paraphimosis as they are often unable to complain of pain. This includes penile ulceration, infection, Fournier's gangrene, and partial penile autoamputation.^{7,8} A careful and complete physical examination is mandatory in these patients. Penile edema secondary to a paraphimosis must be differentiated from edema due to infection, trauma, or allergic reactions.

FIGURE 179-1. The anatomy of a paraphimosis.

ANATOMY AND PATHOPHYSIOLOGY

The foreskin is composed of a double layer of epidermis overlying subcutaneous tissue. It is attached to the skin at the base of the glans penis. The foreskin covers the glans to a variable degree and can usually be completely pulled over the glans. The foreskin is retracted behind the glans and becomes edematous in a paraphimosis. The base of the foreskin is the location of the constricting or phimotic ring (Figures 179-1 and 179-2).

Arterial supply to the foreskin is derived from superficial branches of the external pudendal artery which originate from the femoral artery. These superficial arteries do not communicate with the deep

arteries of the penis. Arterial supply to the glans penis is derived from the paired dorsal arteries of the penis which originate from the penile artery. Dorsal penile arteries run deep to Buck's fascia to enter the glans at the coronal sulcus. **Arterial supply to the glans penis is entirely separate from that of the foreskin.**

A retracted foreskin will block lymphatic drainage from the distal penis. Arterial inflow continues. Lack of lymphatic drainage will cause a progressive edema of the penis distal to the retracted foreskin. The phimotic ring becomes progressively tighter as the foreskin continues to swell. The phimotic ring will eventually obstruct venous outflow. The distal penis will become painful and hyperemic. The edema will progress to ultimately obstruct arterial inflow resulting in penile ischemia, necrosis, and gangrene. This series of events from retraction of the foreskin to arterial inflow obstruction can occur over a few hours to 2 days. The phimotic ring must be advanced (i.e., reduced) over the glans of the penis to relieve the obstruction.

INDICATIONS

All paraphimoses require reduction. The less edematous the tissues will be and the easier it will be to perform the reduction if it is reduced earlier in its time course. **Use nonsurgical techniques first. Surgical techniques are indicated if nonsurgical techniques are unsuccessful or the skin is compromised (i.e., infection, ulceration, or gangrene).**^{6,9,10}

CONTRAINDICATIONS

There are no absolute contraindications to the reduction of a paraphimosis. Certain techniques are contraindicated in specific patient subgroups. Nonsurgical techniques are contraindicated in patients with ulcerated or necrotic foreskins as they may cause iatrogenic injury.^{6,9} Some authors feel that surgical reductions in children should be reserved for Pediatric Urologists.¹¹ **Do not attempt a surgical reduction until noninvasive and lesser invasive techniques have been attempted.** The hyaluronidase technique is contraindicated in penile cancers or infections due to the possibility of spreading infected or malignant cells through the tissue planes.¹²

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- Lidocaine jelly or EMLA cream
- Water-soluble lubricant
- Local anesthetic solution (1% lidocaine or 0.5% bupivacaine) without epinephrine
- 18 gauge needles
- 27 gauge needles
- 10 mL syringe
- 4×4 gauze squares
- Crushed ice
- Surgical gloves
- Babcock clamps, 6 to 8
- 2 inch wide roll of elastic bandage (e.g., Ace Wrap or Elastoplast)
- Sterile drapes
- Sterile surgical gloves
- Suture scissors
- 2 straight hemostats
- #15 surgical blade on a handle

A

B

FIGURE 179-2. A paraphimosis. A. Superior view. B. Inferior view.

- Needle driver
- 3–0 synthetic absorbable suture or chromic catgut suture
- Granulated (table) sugar
- Ampule of D50
- 20% mannitol
- Hyaluronidase, 150 units or 1 mL
- Tuberculin syringe
- Topical antibiotic ointment
- Petrolatum gauze

PATIENT PREPARATION

Reduction of a paraphimosis can be painful and distressing to patients. Explain the risks, benefits, and alternative procedures to the patient and/or their representative. Explain that the progression from nonsurgical to surgical techniques may be required. Obtain an informed consent for the procedure and place this in the medical record. When performing the procedure on a neonate or child, it is advisable to give the parent the option to leave the room or look away as the procedure can be disconcerting to some parents. Leave an indwelling urinary catheter in place during the reduction if the patient has one.

Penile analgesia can sometimes be achieved with topical lidocaine jelly or EMLA cream (i.e., 2.5% prilocaine and 2.5% lidocaine) applied liberally and held in place for 45 to 60 minutes by a biofilm dressing (Chapter 154). A technique especially effective in children involves cutting the finger from a surgical glove, filling it with EMLA cream, and securing this over the penis.¹³ Topical anesthetics often do not provide adequate patient comfort. A ring block or dorsal penile nerve block performed with 0.5% bupivacaine and/or 1% lidocaine, potentially under ultrasound guidance, is becoming accepted as standard of care (Chapters 156 and 177).^{14–16} Procedural sedation (Chapter 159) or general anesthesia may be required.¹¹

TECHNIQUES

The techniques described below to reduce a paraphimosis begin with manual compression and progress to incision of the phimotic ring. They should be attempted in a stepwise manner from least invasive to most invasive in the order presented below.

MANUAL REDUCTION

This method has been extensively described.^{6,11,14,17–21} Liberally apply an anesthetic jelly or water-soluble lubricant to the glans and foreskin. Do not coat the penile shaft or else it will be too slippery to facilitate an easy reduction.

Apply manual compression directly to the glans and edematous foreskin by grasping them with the palm of a gloved hand (**Figure 179-3**). Apply slow and steady pressure for 5 to 10 minutes. Many Emergency Physicians do not have the time or the strength to apply pressure to a patient's penis for 5 to 10 minutes. The parent of young children may be asked to provide the manual compression. Compression may be provided by circumferentially wrapping a bandage around the penis beginning at the glans and working toward the base of the penis.²² Apply the bandage so that it places more pressure distally and less proximally. This will mobilize the edematous fluid from distal to proximal. The bandage can be an Ace Wrap, Elastoplast, or CoFlex gauze soaked in lidocaine jelly or gauze soaked in cold water.^{10,14}

Remove the bandage or release manual compression after it has been applied for 5 to 10 minutes. Apply the index and middle fingers of both hands to surround the top of the penile shaft proximal to

FIGURE 179-3. Manual compression of the glans and foreskin to reduce the edema.

the phimotic ring and the ring fingers underneath the penile shaft (**Figure 179-4**). Place both thumbs adjacent to the urethral meatus (**Figure 179-4**). Push the glans proximally with the thumbs while the fingers simultaneously provide countertraction to pull the phimotic band over the glans. Apply continuous force until the phimotic band moves distal to the glans. This same technique can be applied if the patient has an indwelling urinary catheter (**Figure 179-5**).

Alternatively, encircle the entire foreskin in one hand and pull distally while simultaneously pushing the glans proximally with the thumb of the opposite hand.¹⁷ It is important to be very deliberate in the first attempt as the patient may become more anxious on subsequent attempts. This same technique can be applied if the patient has an indwelling urinary catheter.

ICED GLOVE TECHNIQUE

This technique combines cold to induce vasoconstriction and compression to reduce swelling.^{9,17,21,23} It uses a glove to provide a circumferential ice pack to the foreskin to reduce edema. Half-fill a size 8 surgical glove with crushed ice and cold water. Squeeze the air from the glove and tie a knot in the wrist of the glove. Invaginate the thumb into the body of the glove. Liberally lubricate the glans and foreskin. Insert the penis into the invaginated thumb of the glove.

FIGURE 179-4. Manual reduction of a paraphimosis. The thumbs push the glans proximally while the fingers provide countertraction to slip the phimotic ring over the glans.

FIGURE 179-5. Manual reduction of a paraphimosis in the patient with an indwelling urinary catheter.

Apply manual pressure with a clenched fist or bandage for 5 to 10 minutes. Subsequent manual reduction was found to be successful after icing in 90% of cases.^{9,11,17,23}

BABCOCK CLAMP TECHNIQUE

This technique can be used when manual reduction has been unsuccessful. It has a high rate of success in reducing a paraphimosis.^{10,11,17} **This technique requires penile anesthesia (Chapters 156 and 177). Use only Babcock clamps. All other surgical clamps will crush and devitalize tissue.**

Apply six to eight Babcock clamps circumferentially around the phimotic ring (Figure 179-6A). Place one edge of each clamp just proximal to the phimotic ring and the other edge just distal to the phimotic ring. **It is important to grasp enough tissue of the constricting ring to avoid tearing the skin once traction is applied.**

FIGURE 179-6. The Babcock clamp technique. **A.** Babcock clamps are placed along the phimotic ring. Note that only three Babcock clamps are seen in the illustration for the sake of clarity. **B.** Gentle traction is simultaneously placed on all the clamps to advance the phimotic ring over the glans.

Space the clamps evenly around the circumference of the penis. Grasp all the Babcock clamps in one hand. Simultaneously and slowly apply distal traction to the clamps to pull the phimotic ring over the glans (Figure 179-6B). Remove the Babcock clamps after reduction of the phimotic ring. Examine the foreskin for any signs of traumatic injury from the clamps.

A variation of this technique uses two operators and two Adson forceps in place of Babcock clamps.^{14,24} This method is briefly described for completeness but is not recommended even though it is described in the medical literature. Adson forceps are toothed forceps. Traction with an Adson forceps can result in the teeth pulling through the phimotic ring and tearing the foreskin. One operator applies an Adson forceps to the phimotic ring at the 3 o'clock position and at the 9 o'clock position. The first operator pulls the foreskin distally via the forceps while a second operator compresses the glans and pushes it proximally.

NEEDLE DECOMPRESSION TECHNIQUE

This technique mechanically expresses fluid from the edematous foreskin via a series of puncture holes in the foreskin.^{11,14,20,21,23,25,26} Penile anesthesia is required with this technique. Clean the penis of any dirt or debris. Drape and isolate a sterile field around the penis. Apply povidone iodine or chlorhexidine solution to the penis and allow it to dry. Perform a penile block (Chapters 156 and 177).

Insert a sterile, hollow-bore 18 gauge needle 3 to 5 mm deep into the edematous foreskin. The use of needles as large as 18 gauge to as small as 26 gauge have been described. An 18 gauge is preferred as it makes a hole large enough to allow blood and fluid to escape from the tissues and not close or clot closed. Continue to puncture holes circumferentially around the edematous foreskin (Figure 179-7). An average of 8 to 12 holes are required. Different recommendations exist for as few as 1 to as many as 20 punctures.^{25,26} Wrap a gauze square around the foreskin and glans. Grasp the glans and foreskin in the palm of a gloved hand and apply manual compression. Edema fluid and blood will be expressed from the puncture holes allowing the foreskin to decompress. The gauze square will allow the Emergency Physician to maintain a grasp as the penis becomes slippery with blood and edema fluid. After the foreskin is decompressed, reduce it manually or with Babcock clamps.

DORSAL SLIT OF THE FORESKIN

The Emergency Physician must always be prepared to perform surgical techniques if nonsurgical reduction is unsuccessful. This technique involves the incision of the phimotic ring under strict sterile

FIGURE 179-7. The needle decompression technique.

FIGURE 179-8. The dorsal slit of the foreskin. **A.** The dotted line represents the incision line. **B.** The foreskin opens after the incision is made. The numbers represent the edges of the incision. **C.** The foreskin has been reduced and the edges of the incision sewn shut. A small gap should remain in the midline that is free of sutures. **D.** Alternatively, sew the edges closed with a simple running stitch.

technique.^{14,17-21} Place the patient supine and anesthetize the penis (Chapters 155 and 177) if it has not been done previously. Apply povidone iodine or chlorhexidine solution to the penis and let it dry. Apply sterile drapes to isolate a surgical field. Consider procedural sedation (Chapter 159) prior to performing this technique to alleviate the patient's pain and anxiety.

Clamp a straight-blade hemostat over the foreskin and phimotic ring at the 11 o'clock and 1 o'clock positions. Place one jaw of each hemostat beneath the phimotic ring and the other jaw on top of it. **Be careful not to clamp the skin on the shaft of the penis.** Pull the foreskin taut between the hemostats. Grasp and hold the hemostats with the nondominant hand or have an assistant hold them. Incise the foreskin and phimotic ring at the 12 o'clock position with a scissors or a #15 scalpel blade (**Figure 179-8A**). **Be careful not to cut the skin on the shaft of the penis.** Remove the hemostats. The incision will open into a pentagonal shape (**Figure 179-8B**). Reduce the foreskin over the glans. Cover the penis with sterile gauze and allow the edges of the incision to ooze for 10 to 15 minutes to decompress the foreskin.

This technique can be technically difficult for the non-Surgeon. As an alternative to the two-hemostat technique, a one-hemostat technique may be performed. Place one hemostat over the foreskin and

phimotic ring at the 12 o'clock position (**Figure 179-8A**). Remove the clamp after 1 to 2 minutes. Cut the crushed tissue with scissors through the phimotic ring. **Be careful not to cut the skin on the shaft of the penis.** The foreskin will open up (**Figure 179-8B**).

Reduced the foreskin over the glans after it has been incised. Approximate the cut edges with 3-0 chromic suture using a simple interrupted stitch (**Figure 179-8C**). Sew edge 1 and edge 2 on **Figure 179-8C** together. Sew edge 3 and edge 4 on **Figure 179-8C** together. A gap will remain at the 12 o'clock position that corresponds to the area of the initial incision. Alternatively, sew the cut edges with a simple running stitch (**Figure 179-8D**). Loosely apply petrolatum gauze and gauze squares over the wound. Apply a piece of tape to hold the dressing on the penis. **Do not apply the tape circumferentially as this can result in penile ischemia.**

MODIFIED DORSAL SLIT OF THE FORESKIN

A modified dorsal slit technique has been described where only the phimotic ring is cut rather than the entire foreskin.¹⁷ Clean, prep, anesthetize, and drape the penis as above. A penile block (Chapters 156 and 177) is the preferred method of anesthesia as injection into the distal penis is extremely painful. Infiltrate local anesthetic solution immediately under the phimotic ring at the 12 o'clock position using a 27 gauge needle as an alternative to a penile block. Be sure to raise a wheal both proximally and distally to the phimotic ring (along the dotted line in **Figure 179-9A**).

Incise the phimotic ring with a #15 scalpel blade. **Incise only the phimotic ring. Do not extend the cut more than 3 mm proximally or distally to the phimotic ring.** The foreskin will spring open into a diamond-shaped defect (**Figure 179-9B**). Reduce the foreskin. Cover the penis with gauze and allow the cut edges to ooze for 10 to 15 minutes to decompress the foreskin. Approximate the edges of the wound with 3-0 chromic suture in a running pattern (**Figure 179-9C**). Apply a bandage of petrolatum gauze and gauze squares over the wound. Apply a piece of tape to hold the dressing on the penis. **The tape should not be applied circumferentially as this can cause ischemia to the penis.**

ALTERNATIVE TECHNIQUES

A variety of alternative techniques have been described in the literature. These techniques are variations on the basic principles previously discussed. We will briefly review the osmotic, hyaluronidase, and glans aspiration techniques.

OSMOTIC (SUGAR) TECHNIQUE

An alternative to surgical reduction is the osmotic technique.^{10,14,20,21,23,27,28} It is an innovative and painless but time-intensive

FIGURE 179-9. The modified dorsal slit of the foreskin. **A.** The dotted line represents the incision line. **B.** The foreskin opens after the incision is made. The numbers represent the edges of the incision. **C.** The foreskin has been reduced and the edges of the incision sewn shut.

method. The glans and foreskin are immersed or covered in an osmotic agent such as table sugar, 50% dextrose solution, or mannitol solution. An osmotic gradient is formed between the edematous foreskin and the sugar. The hypertonicity of the sugar draws the edema fluid out of the foreskin. The deflated foreskin can then be manually reduced over the glans. **This technique should not be performed if the foreskin or the glans is infected, gangrenous, or ulcerated.**

Place ordinary table sugar into the invaginated thumb of a large surgical glove. Insert the penis into the thumb of the glove as in the iced glove method. Alternatively, the penis may be wrapped distally to proximally in a gauze square saturated with a 50% dextrose solution or mannitol solution.^{21,28} In all reports, the osmotic agent was left on the penis for at least 1 to 2 hours before manual reduction was successful. **Penile ischemia may be exacerbated by the prolonged time needed to reduce glans edema. The osmotic technique should not be considered a first-line procedure and should only be attempted after manual techniques have failed.**

HYALURONIDASE METHOD

Hyaluronidase (Amphadase, Amphastar Pharmaceuticals Inc., Rancho Cucamonga, CA; Hylenex, Halozyme Therapeutics, San Diego, CA; Vitrase, Ista Pharmaceuticals Inc., Irvine, CA) is a commercially available mammalian enzyme that causes hydrolysis of hyaluronic acid in the intercellular ground substance of connective tissue. It is widely used for subcutaneous hydration (Chapter 140), ophthalmologic surgery, and plastic surgery as a spreading agent. When injected into an edematous foreskin, hyaluronidase increases the tissue permeability, thus allowing the extracellular edema to disperse into the surrounding tissue of the penis and facilitate reduction of the paraphimosis.^{10,12,14,20,21}

Clean, prep, drape, and anesthetize the penis. Inject hyaluronidase subcutaneously using a tuberculin syringe at various points around the circumference of the edematous foreskin. Use a total of 150 units (i.e., 1 mL) of hyaluronidase solution. An alternative is to inject the hyaluronidase into the puncture holes previously made from the needle decompression technique. The edema should resolve almost immediately. Manual compression may be applied to the foreskin for 1 to 2 minutes to help mobilize the fluid. Manually reduce the foreskin after the edema has decreased.

The advantage of this technique is the rapidity with which the edema resolves. Hyaluronidase is contraindicated in patients with penile infections or cancer. It may spread bacteria or malignant cells through the tissue planes. It is contraindicated if the foreskin or glans is gangrenous or ulcerated. Hyaluronidase may not be readily available in many Emergency Departments hindering the applicability of this technique.

GLANS ASPIRATION TECHNIQUE

This method is based on techniques used to treat priapism (Chapter 178).²⁹ The author reports using this technique on four patients with a 100% success rate and no complications. He recommended it for use when the foreskin is very friable and not amenable to vigorous manipulation. This technique is described here for the sake of completeness but is not recommended due to limited evidence.

Clean, prep, drape, and anesthetize the penis. Apply a sterile tourniquet to the penile shaft proximal to the phimotic ring. Use either umbilical tape or a Penrose drain. Insert a 20 gauge needle on a 10 mL syringe into the midline of the glans halfway between the meatus and the corona. Keep the needle and syringe parallel to the urethra. Advance the needle while aspirating with the syringe. Stop advancing the needle once blood is encountered. Continue to

aspirate blood until the glans collapses completely. It is estimated that approximately 3 to 12 mL of blood will need to be aspirated depending on the size of the glans. Remove the needle. Grasp and firmly squeeze the glans with the nondominant hand. Maintain this pressure and release the tourniquet. Manually reduce the foreskin over the collapsed glans with the dominant hand.

ASSESSMENT

The successfully reduced paraphimosis should have the general appearance of a normal uncircumcised penis. The patient usually notes immediate pain relief. It is normal for residual edema to be present. Reassure the patient that the edema will spontaneously resolve over hours to days.^{11,17} Observe the patient in the Emergency Department for 45 to 60 minutes to confirm hemostasis if invasive techniques were used. Observe the patient for full recovery from any sedation or procedural sedation techniques as per hospital policy.

AFTERCARE

Wound care following a surgical reduction is the same as that for any sutured laceration. Many Emergency Physicians do not dress the site at all. The site may be covered with antibiotic ointment or petrolatum gauze followed by a dry sterile gauze.³⁰ Instruct the patient on proper wound care. The patient should inspect the glans and foreskin three to four times a day if Babcock clamps, needle decompression, or surgical techniques were used to reduce the paraphimosis. They should return immediately to the Emergency Department if any signs of infection develop. Advise them to avoid intercourse or masturbation for 4 to 6 weeks.³⁰

Infection after the reduction is an exceedingly rare complication due to the well-vascularized nature of the foreskin. Apply topical antibiotic ointment liberally and recommend it for aftercare. Oral antibiotics are generally not required if the foreskin is abraded by the reduction, torn by the reduction attempts, or torn by the invasive techniques (e.g., Babcock clamp technique, needle decompression, dorsal slit, modified dorsal slit, hyaluronidase technique, or glans aspiration).^{31,32}

All patients should follow-up with a Urologist in 1 to 2 days. Instruct the patient not to retract the foreskin for 1 week after the reduction.⁶ The definitive treatment to prevent recurrence is circumcision. This is typically delayed 7 to 10 days until any edema, inflammation, or ulceration has resolved.^{20,21}

COMPLICATIONS

The most common complication is tearing of compromised penile skin during manual or Babcock clamp reduction. The treatment is to suture any tears that occur and apply antiseptic ointment.^{6,17} Incomplete reduction and pain are possible complications of manual reduction. It is important to allow enough time for adequate dispersion of edema. Manual reduction may be associated with glans contusion and glans ischemia if manual pressure is too great. Cold injury can occur if the iced glove method is not properly monitored during use.⁹

Bleeding is a common complication in this very vascular tissue if surgical techniques are performed. Venous bleeding can be profuse. It is important to have good control of the tissue edges so that adequate hemostatic stitches can be placed. A compressive dressing may aid in hemostasis. Suture the penile shaft if it is lacerated during a surgical reduction. Infection may be a complication of the needle decompression, dorsal slit, modified dorsal slit, hyaluronidase, and glans aspiration techniques.

The glans aspiration method runs the risk of transecting the urethra if the needle is not advanced parallel to the urethra.

Complications of the hyaluronidase method range from minor ecchymoses at the injection site to anaphylaxis and shock if the hyaluronidase is inadvertently injected intravascularly.¹²

SUMMARY

A paraphimosis is a true urologic emergency and a problem that is best prevented. Replacement of the foreskin after urethral catheterization or glans cleaning is important. Early intervention is necessary and can prevent disastrous tissue loss.

There are no randomized controlled trials comparing the efficacy of the various reduction techniques. Our data primarily come from case series that do not demonstrate the superiority of any individual method.²³ Reduction techniques are still best attempted in a step-wise manner beginning with noninvasive methods and progressing to increasingly invasive techniques.

Phimosis Reduction

Kevin O'Rourke

INTRODUCTION

A phimosis is a condition in which the foreskin cannot be retracted proximally to the glans penis.¹⁻¹⁸ The presence of a phimosis can interfere with cleaning under the foreskin, allows the accumulation of secretions and debris (i.e., smegma), and may predispose the patient to infections and possible malignancy.¹⁸ It is classified into two subgroups as physiologic and pathologic. **Physiologic phimoses occur naturally in newborns.** In males younger than 4 years of age, it is normal for the foreskin not to be retractable and it should not be forcibly retracted.¹⁹ In older boys and adults, the foreskin can usually be retracted without difficulty.¹ **A pathologic phimosis is the inability to retract the foreskin after it was previously retractable or after puberty, usually secondary to scarring of the foreskin (Figure 180-1).**^{20,21} Surgical treatment for a phimosis has been known for hundreds of years.² A Byzantine surgeon by the name of Oribasius, in the fourth century AD, gave a seemingly well-acquainted description of a technique involving forced dilation

FIGURE 180-1. A phimosis in an adult. (Used from www.commonswikimedia.org/wiki/Category:Phimosis#/media/File:Glande_intentando_salir.JPG.)

of the constrictive foreskin, scalloping out of its inner surface, then stretching it over a parchment-wrapped lead tube placed between the filleted skin and the glans.² Current techniques for the management of a phimosis in the Emergency Department are simple and remain an important intervention directed at relieving urinary obstruction.

ANATOMY AND PATHOPHYSIOLOGY

At birth there is a physiologic phimosis in the majority of male neonates. This is due to natural adhesions that exist between the foreskin and the glans of the penis. During the first 3 to 4 years of life, the penis grows and epithelial debris (i.e., smegma) accumulates under the foreskin. The debris gradually separates the foreskin from the glans. Intermittent penile erections aid in allowing the foreskin to eventually become retractable. The foreskin of most males will retract easily by the age of 4. **Forcible retraction should be categorically discouraged as this can result in scarring and constriction.**¹ Parents may report that the foreskin bulges during urination which is a normal finding with phimosis. For a nonobstructive phimosis in children, 4 to 6 weeks of topical steroids applied from the tip of the foreskin to the corona of the glans penis have shown excellent results in releasing the stubborn physiologic adhesions between the foreskin and the glans.^{3,4,22,23}

A phimosis can be the cause or the effect of other medical conditions (**Figure 180-1**).²⁴ Recurrent infections (e.g., balanitis or balanoposthitis), repeated urinary catheterization, forceful foreskin retraction, and poor hygiene can lead to scarring of preputial orifices causing a pathologic phimosis. A pathologic phimosis may arise in diabetics due to the presence of glucose in their urine, giving rise to an infection of the foreskin. Once acquired, a phimosis can become a paraphimosis (Chapter 179) if the foreskin is retracted and not promptly reduced. Urinary tract infections can result from bacterial colonization of the phimosis or secondary to urinary obstruction from the phimosis. Males with a pathologic phimosis may report painful erections, hematuria, preputial pain, or a weakened urinary stream. Other complications of a phimosis include recurrent balanitis, local infections, urinary retention, carcinoma of the penis, the easy growth of venereal warts, and the easy acquisition of other sexually transmitted diseases. A phimosis may be the result of local trauma (e.g., zipper injuries, toilet seat trauma, or crush injuries) or the congenital lack of conversion to a mobile foreskin.⁵ Penile carcinoma deserves special mention. Coexistent phimosis is seen in up to 52% of cases of penile carcinoma. **The need for timely follow-up should be impressed upon the patient regardless of the intervention required in the Emergency Department.**⁶

INDICATIONS

The sole indication for the surgical release of a phimosis is urinary obstruction that cannot be relieved by passing a urethral catheter (Chapter 173). A dorsal slit of the foreskin should be performed only after failure of noninvasive techniques. Most patients with a phimosis rarely require any emergency intervention and should be referred to a Urologist on an outpatient basis.

CONTRAINDICATIONS

The ability to pass a urinary catheter (i.e., a Foley or coudé) into the bladder eliminates the acute need for the reduction of a phimosis. Patients with bleeding disorders, gross infections of the foreskin, who are immunocompromised, or who have lesions of the foreskin should have a urinary catheter placed into the bladder (Chapter 173) rather than an incision of the phimotic foreskin. If a catheter cannot

be inserted into the urethra in these patients, a Urologist should be consulted prior to any invasive procedures. Patients with a nonobstructing phimosis should be referred for an elective circumcision and not have a dorsal slit procedure.

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- Gauze squares
- Sterile drapes
- 1% lidocaine without epinephrine
- Lidocaine Uro-jet
- 27 gauge needle
- 5 mL syringes
- Hemostats, straight or straight Kelly clamps
- Urinary catheters (Foley, coudé)
- Sterile gloves
- Sterile drapes
- Scissors
- #15 scalpel blade on a handle
- 3-0 or 4-0 chromic catgut or Vicryl on a noncutting needle
- Needle driver
- Petrolatum gauze
- 1 to 2 inch bandage
- Topical antibacterial ointment

The use of tissue glue of the type normally found in Emergency Departments has been studied in children undergoing circumcision.⁷ It was shown to increase infection, bleeding, and wound dehiscence when compared to suture. The use of suture must be recommended at this time to close the wound edges.

PATIENT PREPARATION

Explain the benefits, risks, potential complications, and aftercare of the procedure to the patient and/or their representative. An informed consent should be obtained and placed in the medical record.

Place the patient supine with their genitalia exposed. Prepare the penis for any intervention. Clean the penis of any dirt, debris, and discharge. Apply drapes to isolate the penis. Apply povidone iodine or chlorhexidine solution onto the penis. If possible, apply the solution under the foreskin using a cotton-tipped applicator. If the patient has pain in the area of the foreskin or if a procedure other than catheter insertion is to be performed, the penis should be anesthetized with a regional nerve block (Chapter 177).^{25,26} Alternatively, infiltration of local anesthetic solution can be used to anesthetize the foreskin. Draw up 5 mL of local anesthetic solution without epinephrine into a syringe armed with a 27 gauge needle. Inject a subcutaneous wheal of local anesthetic solution 2 cm proximal to the distal end of the foreskin. Continue subcutaneous infiltration circumferentially around the penis with the local anesthetic solution. The patient may require intravenous sedation or procedural sedation (Chapter 159) prior to the injection of local anesthetic solution into the penis.

The use of topical anesthetics such as lidocaine jelly, prilocaine creams, or combinations (e.g., EMLA, LET, and LAT) is not recommended.⁸ The application of these mixtures requires an occlusive dressing and 60 to 90 minutes for the anesthetic effect which may then be inadequate.

TECHNIQUES

TOPICAL CORTICOSTEROIDS

Up to 85% of pathologic phimoses that are mild to moderate will respond to the application of topical steroids to the preputial orifice.^{22,23} It is reasonable for the Emergency Physician to prescribe 0.1% to 0.05% betamethasone dipropionate applied twice daily for 4 to 6 weeks with appropriate Urologic follow-up if there is no urinary obstruction or a urinary catheter can be placed.¹¹ The application of topical corticosteroids is the most cost-effective treatment if the circumstances permit.^{19,23}

URETHRAL CATHETERIZATION

Attempt to pass a size 16 or 18 French Foley or coude catheter into the bladder (Chapter 173). If this is too large, attempt to pass the largest possible catheter. Please refer to **Table 176-1** for an age-based list of proper catheter sizes. **Care should be taken to avoid forceful placement of the catheter between the foreskin and the glans.** Correct catheter placement will be confirmed by an outflow of urine.

FORESKIN DILATION

Most simply, the opening of the prepuce can be stretched. The patient's penis should be thoroughly anesthetized prior to performing this procedure (Chapter 177). Consideration should also be given to administering intravenous analgesics, intravenous sedation, or procedural sedation (Chapter 159).

Insert the jaws of a closed hemostat just inside the foreskin. Slowly open the arms of the hemostat slightly (i.e., 2 to 3 mm). **Palpate the foreskin to feel both jaws of the hemostat. If the jaws are not palpable, immediately remove the instrument as one of the jaws may be in the urethra.** If both jaws of the hemostat are palpable, open the arms to dilate the opening of the foreskin. Remove the hemostat. Clean the glans and undersurface of the foreskin with povidone iodine or chlorhexidine solution. Insert, using sterile technique, a urinary catheter if required (Chapter 173).

This approach is not the ideal technique as it carries significant risk of injury to the patient. Inadvertent placement of the hemostat jaw in the urethra can lacerate the urethra and glans of the penis. Dilating the foreskin can cause irregular tears. Injury may require operative intervention and circumcision to correct any iatrogenic trauma.

DORSAL SLIT OF THE FORESKIN

The preferred method to correct an obstructing phimosis in the Emergency Department is the dorsal slit procedure. The patient's penis should be thoroughly anesthetized prior to performing this procedure (Chapter 177). Consideration should also be given to administering intravenous analgesics, intravenous sedation, or procedural sedation (Chapter 159).

Insert the bottom jaw of a straight hemostat between the foreskin and glans at the 12 o'clock position (**Figure 180-2A**). For those individual patients or cultural situations where dorsal incision of the foreskin, much less excision, is cosmetically unacceptable, a ventral approach may be substituted which will yield an apparently uncircumcised penis without obstructive symptoms.⁹ Advance the hemostat until the tip of the jaw is at the coronal sulcus (**Figure 180-2A**) where the foreskin attaches to the penis. Depending on the etiology of the phimosis, adhesions may be encountered. These should gently be broken as the hemostat is advanced. The skin of the prepuce is relatively thin and the jaw of the hemostat should be easily palpated. The tip of the jaw should be seen to tent the skin at the coronal

FIGURE 180-2. Dorsal slit of the foreskin. **A.** A hemostat is inserted under the foreskin and advanced to the coronal sulcus. **B.** The hemostat is elevated to tent the skin and confirm it is properly placed. **C.** The dorsal slit has been made. **D.** The foreskin is retracted. **E.** Interrupted sutures are placed along the cut edge of the foreskin.

sulcus when properly placed (**Figure 180-2B**). **It cannot be over-emphasized that the Emergency Physician must be confident that the instrument has not been inadvertently placed in the urethra. If the jaw of the hemostat cannot be felt and cannot be seen tenting the skin of the foreskin, remove the hemostat and reinsert it.**

Once properly placed, close the hemostat to crush the foreskin at the 12 o'clock position. Allow the hemostat to remain closed for 2 to 3 minutes to thoroughly crush the foreskin. Remove the hemostat. Insert a scissors and advance it with the same attention to position the tip at the coronal sulcus (**Figure 180-2C**). If straight scissors are not available, a #15 blade may be used to cut the crushed skin after another instrument is placed underneath the foreskin to protect the glans from injury. **This method of using a scalpel blade is dangerous and not recommended because control is reduced and the potential for error is unnecessarily increased.**

Retract the cut foreskin. This will leave an open wound edge on both sides of the midline (**Figure 180-2D**). Suture the open wound edges using 3-0 or 4-0 chromic gut suture in an interrupted or running pattern. Begin suturing from the midline to the distal end of the incision (**Figure 180-2E**).⁵ Return the foreskin to its "resting" position to guard against a newly acquired iatrogenic paraphimosis. Generously apply a topical antibacterial ointment over the suture line and loosely cover it with a bandage of petrolatum gauze and gauze squares. Apply a piece of tape to hold the dressing on the penis. **The tape should not be applied circumferentially as this can cause ischemia to the penis.**

Should it be desired, a complete circumcision can be performed after the dorsal slit incision. Using two hemostats, make a series of crushing bites along the foreskin at the level of the coronal sulcus. **Use caution not to crush the skin on the shaft of the penis.** Using scissors, cut the foreskin along the crushed tissue. Approximate the wound edges using 3-0 or 4-0 chromic gut in an interrupted pattern. Carcinoma should always be considered as an etiology of a phimosis and all excised tissue should be sent to pathology for histologic evaluation.¹⁸

ALTERNATIVE TECHNIQUE

PREPUTIOPLASTY

The preputioplasty, although not typically performed in the Emergency Department, is an alternative surgical treatment to the more radical dorsal slit and circumcision. This tissue-sparing surgical technique can achieve full resolution of a phimosis. The preputioplasty is a conservative, less traumatic, and less invasive procedure.

FIGURE 180-3. The prepuce reduction. **A.** Penis with a tight phimotic ring making it difficult to retract the foreskin. **B.** Foreskin retracted under anesthesia with the phimotic ring or stenosis constricting the shaft of the penis and creating a “waist.” The dotted line represents the vertical incision line. **C.** Incision closed laterally with interrupted sutures. **D.** Penis with the loosened foreskin replaced over the glans.

The procedure consists of one or more short longitudinal incisions that release the stenosis and are then closed transversely allowing a widening of the phimotic ring and loosening of foreskin (Figure 180-3).¹³

Clean, prep, anesthetize, and prepare the penis as described previously. Retract the foreskin until it is completely proximal to the glans (Figure 180-3B). The phimotic ring will constrict the penile shaft (Figure 180-3B). Carefully make a superficial incision in the phimotic ring with a #15 scalpel blade or fine scissors (Figure 180-3B). The phimotic ring will open. Allow the wound to ooze for a few minutes. Close the wound using 3-0 or 4-0 chromic gut suture in an interrupted pattern (Figure 180-3C). Return the loosened foreskin over the glans (Figure 180-3D). Generously apply a topical antibacterial ointment over the suture line and loosely cover it with a bandage of petrolatum gauze and gauze squares. Apply a piece of tape to hold the dressing on the penis. **The tape should not be applied circumferentially as this can cause ischemia to the penis.**

ASSESSMENT

Regardless of the technique, observe the patient in the Emergency Department for 45 to 60 minutes to confirm hemostasis. Observe the patient for a full recovery from procedural sedation techniques, if performed, as per hospital policy.

AFTERCARE

The patient may be discharged with Urologic follow-up within 48 hours. Instruct the patient to return to the Emergency Department immediately if the wound is red, has any discharge, or is swollen, or if fever develops. The patient should be given oral analgesics for pain control. Patients should be discharged on oral antibiotics whose spectrum covers skin flora. Cephalexin, 500 mg orally four times a day, is usually adequate. Between discharge and examination by a Urologist, the patient should practice gentle daily washing of the penis with soap, avoid placing any powders or creams in the area, and check the wound three to four times daily for signs of infection. Sexual intercourse and masturbation should be avoided until the incisions have completely healed.

The dorsal slit procedure will result in a “beagle ear”-like deformity. While not problematic in most cases, it may increase the chance of getting the foreskin entrapped in a zipper. The Urologist will often perform an elective circumcision for cosmetic purposes.

COMPLICATIONS

Direct mechanical injury to the glans or urethra by inadvertent placement of instruments into the urethra could be devastating but is easily avoidable by following proper technique. Increased

bleeding may result if the skin is not crushed by the hemostat before it is cut with the scissors.⁵ It is also important to avoid advancing the clamp, and therefore the incision, beyond the comfortable limitation of the coronal sulcus. Otherwise, the skin on the penile shaft will be cut. This can result in a cosmetic defect and possibly skin sloughing requiring a skin graft. Lacerations to the penile shaft skin should be sutured with an absorbable suture. Wound infection and dehiscence are a possibility with any incision and greatly reduced in conscientious patients.

SUMMARY

From a variety of disease processes, the endpoint of a phimosis causing urinary obstruction lends itself to simple correction by the Emergency Physician. If there is not complete urinary obstruction, a trial of topical corticosteroids is simple, cost effective, and may result in the resolution of the phimosis. Careful performance of the described techniques will result in an excellent functional and aesthetic foreskin repair.

Dorsal Slit of the Foreskin

Carlos J. Roldan

INTRODUCTION

Acute conditions affecting the foreskin that must be recognized in the Emergency Department include a phimosis and a paraphimosis. The Emergency Physician must be able to accurately identify and manage these conditions as well as recognize when an urgent Urology consultation is necessary. A dorsal slit of the prepuce or foreskin can be performed in the Emergency Department. This technique is used to relieve strangulation of the glans by a paraphimosis (Figure 181-1) or to aid in the visualization of the urethral meatus in patients with a phimosis (Figure 181-2).¹ The technique is easy to learn and simple to perform.

ANATOMY AND PATHOPHYSIOLOGY

The anatomy of the penis is simple (Figure 181-3). The prepuce, or foreskin, is the skin originating just proximal to the corona that encircles the glans and often extends beyond it.² It may be incomplete, primarily at the ventral midline or the frenulum. The frenulum is the fusion site of the preputial and urethral folds. The glans is composed of the corpus spongiosum that enlarges to cover the tips of the corpora cavernosa. It has less erectile tissue than the corpora cavernosa and contains the urethra.²

The blood supply to the foreskin and glans is provided by the superficial penile arteries. The arteries are derived from the inferior external pudendal arteries which are branches of the femoral arteries. The penile arteries travel in the superficial fascia of the penis and

FIGURE 181-1. A paraphimosis. (Photo courtesy of Eric F. Reichman, PhD, MD.)

FIGURE 181-2. A phimosis. (Used from Plisman at www.commonswikimedia.org.)

above Buck's fascia.³ The left and right superficial penile arteries freely communicate over the midline. Superficial veins accompany the arteries and ultimately drain to the saphenous veins in the thighs. The lymphatics travel deep to Buck's fascia and ultimately empty into the inguinal chain of lymph nodes. The somatic nerves to the foreskin are derived from the pudendal nerves.⁴

A dorsal slit is performed to reduce a paraphimosis or phimosis when other less invasive techniques are unsuccessful. A paraphimosis is the inability to replace the retracted foreskin over the glans into its naturally occurring position (Chapter 179). It is considered an emergency since prolonged retraction of the foreskin creates a constricting ring that quickly compromises vascular and lymphatic circulation with eventual engorgement and necrosis of the glans and foreskin. A phimosis is the inability to retract the distal foreskin over the glans penis (Chapter 180).^{5,6} A phimosis is no longer present once the foreskin can be retracted so that the glans penis partially appears.

INDICATIONS

Perform a dorsal slit of the foreskin to release a paraphimosis or a phimosis if noninvasive and lesser invasive techniques are unsuccessful. A paraphimosis is considered an emergency since prolonged retraction of the foreskin leads to swelling of the prepuce resulting in strangulation injury to the glans.¹ Release a phimosis if it causes urinary retention. The phimotic foreskin should not be forcibly retracted as this can result in a tearing of the foreskin.

CONTRAINDICATIONS

There are no absolute contraindications to the reduction of a paraphimosis. A dorsal slit in children should be performed by a Pediatric Urologist, a Urologist, or after consultation with a Urologist. Perform a dorsal slit in a child for the relief of a paraphimosis only after noninvasive and lesser invasive techniques have been unsuccessfully attempted (Chapter 179).⁷⁻⁹

The ability to pass a urinary catheter (i.e., Foley, coudé, filiforms, and followers) into the bladder eliminates the acute need for reduction of a phimosis (Chapter 173). Place a urinary catheter into the bladder rather than an incision of the phimotic foreskin if possible in patients with bleeding disorders or gross infections of the foreskin, patients who are immunocompromised, or patients who have lesions of the foreskin. Consult a Urologist prior to any invasive procedures if a catheter cannot be inserted into the urethra of

The Anatomy

FIGURE 181-3. Anatomy of the penis. (Photo courtesy of www.peyronies.org.)

these patients. Treat patients with a nonobstructing phimosis with topical corticosteroids and referral for elective circumcision; these patients should not have a dorsal slit procedure in the Emergency Department.

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- Local anesthetic solution without epinephrine
- 5 mL syringe
- 27 gauge needle
- Hemostats, straight or straight Kelly
- #15 scalpel blade on a handle
- Needle driver
- 3–0 or 4–0 sutures (i.e., chromic catgut, Dexon, or Vicryl)
- Petrolatum gauze
- Metzenbaum scissors
- Suture scissors
- 4 × 4 gauze squares
- Sterile gloves
- Sterile drapes
- Topical antibacterial ointment

The use of tissue glue of the type normally found in Emergency Departments has been studied in children undergoing circumcision.¹⁰ It was shown to increase infection, bleeding, and wound

dehiscence when compared to suture. The use of suture is highly recommended to close the wound edges after the release of a paraphimosis or a phimosis.

PATIENT PREPARATION

Explain the risks, benefits, and alternative procedures to the patient and/or their representative. Obtain an informed consent for the procedure and place this in the medical record. When performing the procedure on a neonate or child, it is advisable to give the parent the option to leave the room or look away as the procedure can be disconcerting to some parents.

Prepare the penis for any intervention. Clean the penis of any dirt, debris, and discharge. Apply drapes to isolate the penis. Apply povidone iodine or chlorhexidine solution onto the penis. Apply the solution under the foreskin using a cotton-tipped applicator if it is possible. Anesthetize the penis (Chapter 177) if the patient has pain of the foreskin or if a procedure other than catheter insertion is to be performed. An alternative is the infiltration of local anesthetic solution. Draw up 5 mL of local anesthetic solution without epinephrine into a syringe armed with a 27 gauge needle. Inject a subcutaneous wheal of local anesthetic solution 2 cm proximal to the distal end of the foreskin. Continue subcutaneous infiltration circumferentially around the penis with the local anesthetic solution. The patient may require intravenous sedation or procedural sedation (Chapter 159) prior to the injection of local anesthetic solution into the penis.

The use of topical anesthetics (Chapter 154) such as lidocaine jelly, prilocaine creams, or combinations (EMLA, LET, LAT) is not recommended.¹¹ The application of these mixtures requires an

occlusive dressing and 60 to 90 minutes for the anesthetic effect which may then be inadequate. Their use will delay the performance of the procedure.

TECHNIQUES

DORSAL SLIT OF THE PARAPHIMOTIC FORESKIN

Always be prepared to perform surgical techniques if nonsurgical reduction is unsuccessful. This technique involves the incision of the phimotic ring using strict sterile technique.¹²⁻¹⁴ Place the patient supine and anesthetize the penis if it has not been done previously. Apply povidone iodine or chlorhexidine to the penis and let it dry. Apply sterile drapes to isolate a surgical field. Consider the administration of parenteral sedation prior to performing this procedure to alleviate the patient's anxiety.

Clamp a straight-blade hemostat over the foreskin and phimotic ring at the 11 o'clock and 1 o'clock positions. Place one jaw of each hemostat beneath the phimotic ring and the other jaw on top of it. **Be careful not to clamp the skin on the shaft of the penis.** Pull the foreskin taut between the hemostats. Grasp the hemostats with the nondominant hand or have an assistant hold them. Incise the foreskin and phimotic ring at the 12 o'clock position with a scissors or #15 scalpel blade (**Figure 181-4A**). **Be careful not to cut the skin on the shaft of the penis.** Remove the hemostats. The incision will open into a pentagonal shape (**Figure 181-4B**). Reduce the foreskin over the glans. Cover the penis with sterile gauze and allow the edges of the incision to ooze for 10 to 15 minutes.

This technique can be technically difficult to perform. A one-hemostat technique may be performed as an alternative to the two-hemostat technique. Place one hemostat over the foreskin and phimotic ring at the 12 o'clock position (**Figure 181-4A**). Remove the clamp after 1 to 2 minutes. Cut the crushed tissue with scissors through the phimotic ring. **Be careful not to cut the skin on the shaft of the penis.** The foreskin will open as described (**Figure 181-4B**). Bloody edematous fluid will ooze out and this can be sponged. Reduce the foreskin over the glans. **A total reduction of the paraphimosis must be accomplished to obtain satisfactory**

results. Cover the penis with sterile gauze and allow the edges of the incision to ooze for 10 to 15 minutes.

Approximate the cut edges with 3-0 chromic suture using a simple interrupted stitch after the foreskin has been incised and reduced over the glans (**Figure 181-4C**). Sew edge 1 and edge 2 on **figure 181-4C** together. Sew edge 3 and edge 4 on **figure 181-4C** together. A gap will remain at the 12 o'clock position that corresponds to the area of the initial incision. Alternatively, sew the cut edges with a simple running stitch (**Figure 181-4D**). Loosely apply petrolatum gauze and gauze squares over the wound. Apply a piece of tape to hold the dressing on the penis. **The tape should not be applied circumferentially as this can cause ischemia to the penis.**

MODIFIED DORSAL SLIT OF THE PARAPHIMOTIC FORESKIN

A modified dorsal slit technique has been described where only the phimotic ring is cut rather than the entire foreskin.^{12,15} Clean, prep, anesthetize, and drape the penis as described previously. A penile block is the preferred method of anesthesia because injection onto the distal penis is extremely painful. An alternative to a penile block is to infiltrate under the phimotic ring at the 12 o'clock position with local anesthetic solution without epinephrine using a 27 gauge needle. Be sure to raise a wheal both proximally and distally to the phimotic ring (along the dotted line in **Figure 181-5A**).

Incise the phimotic ring with a #15 scalpel blade. **Incise only the phimotic ring. Do not extend the cut more than 3 mm proximally or distally to the phimotic ring.** Once incised, the foreskin will spring open into a diamond-shaped defect (**Figure 181-5B**). Reduce the foreskin. Cover the penis with gauze and allow the cut edges to ooze for 10 to 15 minutes to decompress the foreskin. Approximate the edges of the wound with 3-0 chromic suture in an interrupted or running pattern (**Figure 181-5C**). Apply a bandage of petrolatum gauze and gauze squares over the wound. Apply a piece of tape to hold the dressing on the penis. **The tape should not be applied circumferentially as this can cause ischemia to the penis.**

DORSAL SLIT OF THE PHIMOTIC FORESKIN

The preferred method to correct an obstructing phimosis in the Emergency Department setting is the dorsal slit procedure. The patient's penis should be thoroughly anesthetized prior to performing this procedure. Consideration should also be given to administering intravenous analgesics, intravenous sedation, or procedural sedation.

Insert the bottom jaw of a straight hemostat between the foreskin and glans at the 12 o'clock position (**Figure 181-6A**). A ventral approach may be substituted. This will yield an apparently uncircumcised penis without obstructive symptoms. For those individual patients or cultural situations where dorsal incision of the foreskin, much less excision, is cosmetically unacceptable.¹² Advance the hemostat until the tip of the jaw is at the coronal sulcus (**Figure 181-6A**). The coronal sulcus is where the foreskin attaches to the penis. Adhesions may be encountered depending on the cause of the phimosis. Gently break the adhesions as the hemostat is advanced. The skin of the prepuce is relatively thin and the jaw of the hemostat is easily palpated. Visualize the tip of the jaw tenting the skin at the coronal sulcus when properly placed (**Figure 181-6B**). **It cannot be overemphasized that the Emergency Physician must be confident that the instrument has not been inadvertently placed in the urethra. Remove the hemostat and reinsert it if the jaw of the hemostat cannot be felt and cannot be seen tenting the skin of the foreskin.**

Close the hemostat once properly placed. Allow the hemostat to remain closed for 2 to 3 minutes to crush the skin. Remove the

FIGURE 181-4. Dorsal slit of the paraphimotic foreskin. **A.** The dotted line represents the incision line. **B.** The foreskin opens after the incision is made. The numbers represent the edges of the incision. **C.** The foreskin has been reduced and the edges of the incision sewn shut. A small gap should remain in the midline that is free of sutures. **D.** Alternatively, sew the edges closed with a simple running stitch.

FIGURE 181-5. Modified dorsal slit of the paraphimotic foreskin. **A.** The dotted line represents the incision line. **B.** The foreskin opens after the incision is made. The numbers represent the edges of the incision. **C.** The foreskin has been reduced and the edges of the incision sewn shut.

hemostat. Insert a scissors and advance it with the same attention to position the tip at the coronal sulcus. Incise the crushed tissue to the level of the coronal sulcus (**Figure 181-6C**). A #15 blade may be used to cut the crushed skin after another instrument is placed underneath the foreskin to protect the glans from injury. **This method of using a scalpel blade is dangerous and not recommended because control is reduced and the potential for error is unnecessarily increased.**

Retract the cut foreskin. This will leave an open wound edge on both sides of the midline (**Figure 181-6D**). Cover the penis with gauze and allow the cut edges to ooze for 10 to 15 minutes. Approximate the open wound edges using 3-0 or 4-0 chromic gut suture in an interrupted or running pattern. Begin suturing from the midline to the distal end of the incision (**Figure 181-6E**).¹² Return the foreskin to its “resting” position to guard against a newly acquired iatrogenic paraphimosis. Apply a bandage of petrolatum gauze and gauze squares over the wound. Apply a piece of tape to hold the dressing on the penis. **The tape should not be applied circumferentially as this can cause ischemia to the penis.**

ASSESSMENT

The foreskin is now be retractable to a sufficient degree to allow visualization of the meatus when performed for a phimosis or reduced over the glans to relieve pressure when performed for a paraphimosis. The successfully reduced paraphimosis should have the general appearance of a normal uncircumcised penis. It is normal for residual edema to be present. Reassure the patient that the edema will spontaneously resolve over hours to days. Observe the patient in the Emergency Department for 45 to 60 minutes to

FIGURE 181-6. Dorsal slit of the phimotic foreskin. **A.** A hemostat is inserted under the foreskin and advanced to the coronal sulcus. **B.** The hemostat is elevated to tent the skin and confirm it is properly placed. **C.** The dorsal slit has been made. **D.** The foreskin is retracted. **E.** Interrupted sutures have been placed in the cut edges of the foreskin.

confirm hemostasis. Observe the patient for a full recovery from any sedation or procedural sedation techniques as per hospital policy.

AFTERCARE

Wound care following a surgical reduction is the same as that for any sutured laceration. Many physicians do not dress the incision site. It may be covered with antibiotic ointment or petrolatum gauze and dry sterile gauze.¹¹ Counsel the patient on proper wound care. The patient should inspect the glans and foreskin three to four times a day. They should return immediately to the Emergency Department if any signs of infection develop. Advise the patient to avoid intercourse or masturbation for 4 to 6 weeks.¹¹

Prescribe antibiotics that cover gram-positive organisms. An extended-spectrum penicillin or first-generation cephalosporin is most frequently prescribed. Cephalexin, 500 mg orally four times a day, is usually adequate.

All patients need to follow-up with a Urologist in 1 or 2 days. The definitive treatment is circumcision, which is typically delayed 7 to 10 days until any edema, inflammation, or ulceration has resolved.^{13,14,16}

COMPLICATIONS

Direct mechanical injury to the glans or urethra by inadvertent placement of instruments into the urethra could be devastating but is easily avoidable by following proper technique. Increased bleeding may result if the skin is not crushed by the hemostat before it is cut with the scissors. It is also important to avoid advancing the clamp, and therefore the incision, beyond the comfortable limitation of the coronal sulcus. The skin on the penile shaft will otherwise be cut. This can result in a cosmetic defect and possibly skin sloughing requiring a skin graft. Wound infection and dehiscence are a possibility with any incision and greatly reduced in conscientious patients.

Bleeding is a common complication in this very vascular tissue. Venous bleeding can be profuse and it is important to have good control of the tissue edges so that adequate hemostatic stitches can be placed. A compressive dressing may aid in hemostasis. Suture the penile shaft if it is lacerated during a surgical reduction.

SUMMARY

A dorsal slit is an easy and rapid way to relieve strangulation pressure from a paraphimosis or to allow visualization of the urethral meatus from an obstructing phimosis. This procedure is performed primarily in emergency situations as the cosmetic result is usually suboptimal. Refer patients able to urinate with a phimosis to a Urologist before performing a dorsal slit. The dorsal slit procedure

should only be performed when a phimosis is obstructing and a urethral catheter cannot be placed. A paraphimosis is always an emergency. Often this will reduce with less invasive techniques that should be attempted first. Severe cases will require a dorsal slit.

Manual Testicular Detorsion

Steven Go

INTRODUCTION

Testicular torsion was first described in the English literature in 1907.¹ Testicular torsion occurs when the testicle twists around its axis and causes vascular compromise of the testicle (Figure 182-1). **Testicular torsion is a clinically diagnosed and time-sensitive emergency.** The goal of the Emergency Physician is to suspect the diagnosis, make the diagnosis, and facilitate rapid operative detorsion by a Urologist. Manual detorsion can be attempted while awaiting surgical intervention.

The incidence of testicular torsion is approximately 3.5 to 4.5 in 100,000 males < 25 years of age.^{2,3} It primarily affects young persons with a bimodal age distribution. The most common occurrence is in the neonatal period with the second peak at approximately age 13.⁴ Most cases of testicular torsion occur in patients < 21 years of age.⁵

FIGURE 182-1. Torsion of the right testicle. The testicle lies horizontally and in a higher position than the normal testicle.

Rare cases of testicular torsion in men > 59 years of age have been reported.⁶⁻⁹ The age range at risk for torsion is broader than commonly thought.

Testicular torsion cannot be ruled out by history and physical examination.^{10,11} There are commonly associated history and physical examination features. Testicular torsion classically presents with acute onset of excruciating pain in the unilateral testicle or scrotum. Cases of bilateral testicular torsion can occur.¹² Testicular torsion may be associated with a recent history of genital trauma including self-mutilation in up to 8% of cases.^{13,14} Associated symptoms may include a low-grade fever, nausea, and vomiting.^{15,16} A history of a prior orchiopexy (i.e., surgical fastening of the testicle) does not exclude a testicular torsion.¹⁷ Patients may present immediately upon the onset of pain or days later. Delayed presentation can sometimes occur in patients who have a history of chronic intermittent torsion.

Patients typically have testicular pain to palpation and a painful, edematous scrotum. The testicle can present with a high-riding horizontal lie with anterior rotation of the epididymis (Figure 182-1).^{16,18,19} This testicle positioning is not universal.¹⁰ A cremasteric reflex was typically absent in one trial.²⁰ The cremasteric reflex remains present in testicular torsion in 8% to 40% of cases.¹⁹⁻²⁴ Prehn's sign (i.e., relief of pain with elevation of the scrotum) is classically present in epididymitis and absent in testicular torsion. It too is an imperfect discriminator.²⁵⁻²⁸ Color Doppler ultrasound (US) studies can be misleading because scrotal blood flow can be misinterpreted as testicular blood flow.^{11,29} A lack of flow assumes testicular torsion is present with a sensitivity of 45% to 60%.³⁰

Color Doppler US is the initial test of choice because of its greater availability, lower cost, lack of adverse effects, and no ionizing radiation. It has largely replaced testicular radionuclide scintigraphy for the confirmation of testicular torsion.³¹ **Emergent consultation with a Urologist should not be delayed for the results of a radiologic study when testicular torsion is strongly suspected because outcomes worsen the longer detorsion is delayed.**³²⁻³⁴ Color Doppler US has a reported sensitivity for testicular torsion of only 85.7% to 90%.³⁵⁻³⁸ This sensitivity may be improved by examination of the spermatic cord to the level of the internal ring.³⁹ **Color Doppler US cannot completely exclude testicular torsion. The patient should be surgically explored by a Urologist if testicular torsion is strongly suspected and no other competing diagnosis can be definitively confirmed by color Doppler US.**²⁹

Image the testes and spermatic cord to the abdomen if using US.⁴⁰⁻⁴² Look at the gray scale appearance, Doppler of arterial and venous flow, and the arterial Doppler waveform (Figures 182-2

FIGURE 182-2. Gray scale US image showing abnormal hypoechoogenicity in the right testicle (left side of picture) and a normal left testicle (right side of picture) for comparison. (Photo used with permission from www.iame.com.)

through 182-4). Compare the normal testes to the torsed testes. Gray scale may show the torsed testicle to be enlarged, edematous, and heterogenous (Figure 182-2). Arterial and venous Doppler flow may be decreased or absent (Figure 182-3). Look for kinking or coiling of the spermatic cord. Blood flow to the normal testicle should persist throughout diastole. An increased flow during systole decreases gradually in diastole. Increased flow is seen in epididymo-orchitis and torsion-detorsion. Hyperdynamic flow is seen after detorsion. Power Doppler waveforms show decreased or no flow in the arteries (Figure 182-4). US can identify other etiologies of testicular pain (e.g., hydrocele).

Scoring systems that involve clinical characteristics with or without US findings have been developed to detect testicular torsion and reduce the need for color Doppler US.^{20,28,43} These studies were limited by small sample sizes and the use of non-Emergency Medicine providers to score patients. These scoring systems must await

FIGURE 182-3. Color Doppler US image showing no flow in the right testicle (left side of picture) and normal flow in the left testicle (right side of picture). (Photo used with permission from www.iame.com.)

FIGURE 182-4. Color spectral Doppler US image showing the normal arterial flow in the right testicle (left side of picture) and no flow in the left testicle (right side of picture). (Photo used with permission from www.iame.com.)

prospective, multicenter external validation before they can be recommended for widespread use.

The differential diagnosis of the acute scrotum includes acute idiopathic scrotal edema, appendicitis, cellulitis, epididymitis, epididymo-orchitis, Fournier's gangrene, Henoch-Schönlein purpura, hernias, hydroceles, infections, inguinal hernia, mumps, orchitis, testicle appendage torsion, trauma, tumor, varicoceles, and vasculitis (Table 182-1).^{29,34,41,44} Testicular torsion is the most time-dependent of these conditions. **Consider testicular torsion first in the evaluation of the acute scrotum. Consult a Urologist immediately for a bedside evaluation and manual detorsion while awaiting more definitive intervention.**⁴⁵

ANATOMY AND PATHOPHYSIOLOGY

The testicle is covered by the tunica albuginea. Underneath the tunica albuginea is the visceral layer of the tunica vaginalis. The parietal layer of the tunica vaginalis partially encloses the testicle and the epididymis. The testicular (i.e., spermatic) artery acts as the primary blood supply to the testicle and traverses the spermatic cord. Venous drainage is supplied by the pampiniform plexus within the spermatic cord. The above structures, as well as the vas deferens, are enveloped by the cremaster muscle and fascial layers.

There are two basic types of testicular torsion. They are intravaginal and extravaginal.⁴⁶ **An intravaginal torsion is the most common type of testicular torsion.** It occurs when the testicle twists within the tunica vaginalis. The classic anatomic abnormality that predisposes to intravaginal torsion is the "bell clapper" deformity which occurs when the tunica vaginalis inserts high on the spermatic cord (Figure 182-5).⁴¹ This allows the testes to assume a horizontal lie and resembles the way a bell clapper sits in the housing of a bell. This abnormality allows the testicle to twist within the tunica vaginalis. **Extravaginal torsion occurs mostly in neonates and the testicle twists outside the tunica vaginalis.** The etiology and anatomic predisposing factors for extravaginal torsion are not currently known.^{23,47}

The spermatic cord becomes twisted when the testicle twists. Venous flow is compromised first and results in edema. Arterial occlusion soon follows and testicular ischemia is the result. **The pathologic changes proceed along a spectrum from congestion to hemorrhagic infarction depending on the duration of the**

TABLE 182-1 The Characteristics of Common Presentations of Acute Testicular Pain

Characteristic	Epididymitis	Testicular appendage torsion	Testicular torsion
Dysuria	Possible but unlikely	Possible but unlikely	Possible but unlikely
Cremasteric reflex	Absent or present	Absent or present	Absent or present
Fever	Possible, especially in advanced disease	Possible but unlikely	Possible but unlikely
History of trauma	Possible	Possible	Possible
Swelling and tenderness	Epididymis, progressing to hemiscrotum	Epididymis or head of testicle	Testicle, progressing to hemiscrotum
Nausea and vomiting	Possible but unlikely	Possible but unlikely	Possible
Pain onset	Gradual	Gradual or sudden	Sudden
Patient age	Primarily adolescents and adults Can occur at any age	Prepuberty typically	Bimodal in neonates and adolescents Can occur at any age
Prior pain episodes	None	Sometimes	Sometimes with spontaneous detorsion
Pyuria	Possible but unlikely	Possible but unlikely	Possible but unlikely
Risk factor(s)	Genitourinary abnormalities Genitourinary instrumentation Promiscuity Sexual activity	Testicular appendages	Orchiopexy failure Rapid increase in testicle size in adolescent Undescended testicle
Testicle position	Normal Aligned vertically	Normal Aligned vertically	High-riding Aligned transversely

ischemia.²³ The time to permanent damage is not precisely known. Most authors believe that the testicle should be detorsed within 6 hours of onset for the best results.^{11,48} The literature contains reports of good outcomes in testes that have been torsed for up to 48 hours.^{10,11,34} Incomplete torsions exist and some blood flow to the testicle may be preserved. **Do not assume a testicle is not viable based on the timing of pain onset alone.**

It has been thought that there are negative effects of testicular torsion on spermatogenesis in the contralateral testicle. The published data are conflicted.⁴⁹⁻⁵² Studies demonstrating negative effects have relied on flawed surrogate markers of testicular function. More recent literature has demonstrated no residual effect on contralateral spermatogenesis.⁵² It is not clear at present whether testicular torsion causes long-term functional damage to the contralateral testicle.

INDICATIONS

Preoperative manual detorsion is associated with improved testicular salvage.^{48,53} **Attempt manual reduction of a suspected torsed testicle while awaiting the arrival of the Urologist.** This procedure was first described by Nash in 1893 and involves rotating the testicle

in attempt to untwist the spermatic cord and restore blood flow.⁵⁴ There is minimal downside to attempting this procedure if it does not delay definitive surgical management.⁴⁵ Manual detorsion may be difficult due to edema.

CONTRAINDICATIONS

There are no absolute contraindications to attempting manual detorsion. The detorsion attempt may not be successful for various reasons (e.g., poor patient tolerance of the procedure or an already necrotic testicle fixed to the scrotal wall).⁴⁸ **An attempt at manual detorsion must not delay surgery.** Some patients may have contraindications to parenteral pain relief and sedation that may be required for the procedure.⁵⁵ **The immediate availability of a Urologist and operative management precludes attempts at manual detorsion.**

EQUIPMENT

No special equipment is required to manually attempt detorsion of a testicle. It is likely that parenteral analgesia and possibly procedural sedation may be necessary (Chapter 159). The use of color Doppler

FIGURE 182-5. The normal testicle (left) and tunica vaginalis (purple) versus the bell clapper deformity (right). (Photo used with permission from A.K. Saxena, MD.)

US to assist with the determination of a successful detorsion is optimal but not required. The absence of an US machine should not preclude detorsion attempts if otherwise indicated.

PATIENT PREPARATION

Assess the patient's (or their representative's) capacity to consent for the manual detorsion. Carefully explain the procedure, potential benefits (i.e., restoration of blood flow with possible improved outcomes and relief of pain), risks (i.e., transient pain during the procedure or inability to resolve the torsion), and alternatives (i.e., wait for surgical detorsion). **Make the patient aware that a successful procedure does not guarantee a good outcome.** Explain that sedation is an option. It would be ideal for the patient to be able to communicate to ascertain the efficacy of the detorsion attempts. Ensure the patient and/or their representative understands that they will require a subsequent operation regardless of the outcome of the manual detorsion attempt to lessen the chances of a future torsion or to attempt to salvage the testicle if manual detorsion fails.¹⁵ Inform the patient they will be kept nil per os (NPO; nothing by mouth). Document the informed consent in the medical record.

Anesthesia is not absolutely contraindicated. Insert an IV for vascular access. Place the patient on the cardiac monitor, noninvasive blood pressure cuff, pulse oximetry, and supplemental oxygen to monitor them during and after the procedure if sedation is to be administered. It is preferred not to perform a spermatic cord block or overly sedate the patient because the patient's pain response is used to help indicate if the testicle is being turned in the correct direction and when blood flow has been improved.⁵⁶ The injection of local anesthetic can further compromise testicular blood flow.⁵⁷ Some patients are in so much pain that they may require a block and/or procedural sedation to even make the attempt at manual reduction. **Pay careful attention in these cases to the restoration of normal anatomy to determine that detorsion has occurred.**⁵⁸ A color Doppler US is useful to confirm the clinical impression.

Place the patient supine with the bed set at a level comfortable for the Emergency Physician. The testicle can be manually reduced if standing is more comfortable for the patient. **The standing position is a contraindication to analgesia, parenteral sedation, or procedural sedation as the patient may fall.**

TECHNIQUE

The direction of most torsions has been described as inward or medial. The initial detorsion attempt should be in an outward or lateral direction (Figure 182-6). This motion is like "opening a

book" with thumbs or rotation of the hand from pronation to supination.^{56,59} The patient's left testicle is turned clockwise while the right testicle is turned counterclockwise (Figure 182-6).⁵⁶

There is no evidence-based preferred technique or grip in rotating the testicle. It is simply a matter of placing the patient in a comfortable position and achieving a secure but gentle grip on the affected testicle. Stabilize the spermatic cord with the other hand to prevent it from moving. **Rotate the torsed testicle within the scrotum 90° at a time outward (Figure 182-6). There should be no resistance.** Reevaluate the patient's pain, testicle position, and arterial flow using US.

Resistance to manual detorsion or worsening of the pain indicates that the testicle should be turned in the opposite direction of the initial attempt.⁴⁸ Approximately 33% of testicular torsions are lateral instead of medial.^{15,60} Some authors have maintained the need to rotate the torsed testicle in two planes (caudal to cranial and medial to lateral).⁵⁸ Others have reported success with single plane rotation.⁴⁶

The degree of torsion ranges from 180° to 1080°, with a median torsion of 360° to 540°.¹⁵ **Continue the manual detorsion until the pain is relieved and the normal anatomy is restored if no resistance or increased pain is encountered.**⁴⁶

ASSESSMENT

Successful detorsion is indicated by immediate relief of pain and the restoration of the normal anatomy. Relief of pain alone is not adequate to ensure complete detorsion. Normal anatomy is indicated by a lengthening of the spermatic cord, a softening of the involved testicle, and a restoration of a normal vertical lie of the testicle.⁵⁸ Use color Doppler US if available to verify the restoration of blood flow after the detorsion attempt. Reperfusion may alter vascular flow patterns which may obscure the color Doppler US results.²³ Continue manual detorsion until the pain is relieved, the normal anatomy is restored, and flow is seen on the US.

AFTERCARE

Every testicular torsion patient should receive an emergent Urologist consult and be scheduled for surgery regardless of the results of the manual detorsion.⁴⁵ Surgery is required even with pain relief because the testicular torsion may not have been completely reduced. Bilateral orchiopexy is indicated to try to prevent future episodes since approximately 80% of patients with the "bell clapper" deformity have the deformity in the contralateral testicle.²³ The exact timing of the surgery will be influenced by the outcome of detorsion attempts and the Urologist.^{61,62}

COMPLICATIONS

There are a few minor complications to manual detorsion but none that should deter the Emergency Physician from an attempt at detorsion should it be indicated. The procedure is painful. Detorsion in the wrong direction will initially increase the patient's discomfort. The injection of local anesthetic solution into the spermatic cord may further compromise testicular blood flow if a spermatic cord block is performed. There is the possibility that, despite proper technique, the Emergency Physician will be unable to detorse the testicle. The patient will have endured an uncomfortable procedure without gain if testicular torsion is not the correct diagnosis. Detorsion in the wrong direction may temporarily increase the degree of vascular compromise. Detorsion should cause no increase in ischemia if detorsed in the opposite direction. Complications may arise from a delay in notification of the Urologist.⁵⁶

FIGURE 182-6. Manual detorsion of a testicle. The arrows represent the directions to initially attempt to rotate the testicle.

A more serious potential complication stems from the false sense of security obtained when the patient has pain relief. Manual detorsion may only partially restore blood flow and rapid surgical intervention may still be required. Delaying the trip to the Operating Room due to lack of pain may cause “castration by procrastination.”⁵⁶

Animal studies suggest that detorsion of an ischemic testicle can cause neurohormonal-mediated reperfusion damage.⁶³⁻⁶⁵ A variety of substances are being investigated to see if this damage can be prevented.⁶⁵⁻⁷⁰ These findings await confirmation in humans. Experimental data should not be used to justify inaction by the Emergency Physician.

SUMMARY

Emergency Physicians should suspect, recognize, and aggressively treat testicular torsion. Swift action is necessary to preserve function since “time is testicle.” Consult a Urologist immediately when testicular torsion is strongly suspected. Attempt manual detorsion on all patients while awaiting definitive surgical management. The patient needs surgery to confirm the restoration of full blood flow even if manual detorsion is successful and for bilateral orchiopexy to reduce the chances of torsion in the future.

Zipper Injury Management

Anthony W. Catalano and Ricky N. Amii

INTRODUCTION

Zipper injuries may involve any area of exposed skin.¹⁻²¹ Zipper injuries usually occur to the foreskin, the skin of the penis, and the scrotum. Zipper injuries result in skin and soft tissue entrapment when the zipper is opened or closed. It primarily occurs in uncircumcised young boys, intoxicated adults, the mentally handicapped, males not wearing underwear, and elderly men suffering from movement or cognitive disorders. The most common type of zipper entrapment compresses the skin between the sliding piece (fastener mechanism) and the teeth of the zipper. Another type of entrapment involves the skin between the teeth of the zipper after the sliding piece has moved beyond the area.^{1,2} Multiple methods to extract the entrapped skin have been reported.¹⁻²¹ These methods

range from manipulation to tooth-by-tooth extraction to circumcision. Significant swelling can obscure the zipper mechanism and make standard approaches impossible necessitating ingenuity to avoid secondary injury.¹⁶ Treatment should be guided by the type of entrapment.¹ Removal of the zipper can be performed quickly using basic tools to extract the entrapped tissue and thus prevent or limit secondary injury.

ANATOMY AND PATHOPHYSIOLOGY

The zipper is a simple device that is used daily by millions of people (**Figure 183-1**). Although universally present on clothing and equipment, the simple zipper mechanism may be difficult to conceptualize. It consists of a sliding piece that moves in two directions. The sliding piece is composed of a front and back plate connected by the median bar (**Figures 183-1B and 183-1C**).⁵ Each plate has a small raised edge that helps to guide the two rows of teeth together (**Figures 183-1B and 183-1C**). These edges do not connect to each other as the only portion of contact between the two plates is via the median bar. **Without this bar the mechanism falls apart.** The median bar is usually located at the top of the sliding piece. A finger grip is attached to the front plate of the sliding piece and functions as a handle to move the sliding piece. The teeth are two opposing sets of rectangular metal or plastic pieces attached to fabric to keep them aligned (**Figures 183-1A and 183-1D**). Moving the sliding piece across an open zipper will interlock the teeth and close the zipper. Reversing the sliding piece direction will unlock the teeth and open the zipper. The importance of this interdigitating order is evident when this back-and-forth order is violated and the sliding piece cannot pass the defect without great force, if at all.

Although any area of skin can become entrapped in a zipper, it primarily occurs to the foreskin, penis, and scrotum. Entrapment often occurs in those who are in a rush to get dressed, not wearing underwear, intoxicated, or in a rush to zip up their pants. Zipper injuries can be extremely painful. Patients are often unable to undo the entrapment themselves and present to the Emergency Department for help. Because this is an embarrassing injury, patients often present after attempts at self-extraction and a few hours after the injury. Delays in seeking medical care may result in significant edema that can complicate the removal of the entrapped tissue.

INDICATIONS

Skin entrapped between the sliding piece and teeth or between the teeth of the zipper must be extricated. The skin should be released as soon as possible to minimize edema and prevent necrosis.

CONTRAINDICATIONS

There are no absolute contraindications to the removal of a zipper, the slider, or the teeth from an entrapped piece of skin. Consult a Urologist after releasing the entrapment in cases of significant edema, skin necrosis, urethral involvement, or infection.

EQUIPMENT

- 25 or 27 gauge needle
- Syringes (3, 5, and 10 mL)
- Scissors, bandage or Mayo
- Scissors, small or iris
- Topical anesthetic (e.g., EMLA cream or viscous lidocaine)

FIGURE 183-1. Anatomy of a zipper. **A.** Artist illustration of a zipper. **B.** Front view of the sliding mechanism. **C.** Side view of the sliding mechanism. **D.** Artist illustration of zipper close up. (Used from [www.commonswikimedia.org/wiki/File:Zipper_animated_\(reversed\).gif](http://www.commonswikimedia.org/wiki/File:Zipper_animated_(reversed).gif) by Dominique Toussaint.)

- Local anesthetic solution without epinephrine
- Mineral oil or other lubricant (e.g., surgical lubricant)
- Antibiotic ointment
- Needle driver
- Dremel tool
- Nail lifter or flathead screwdriver
- Pliers
- Heavy-duty wire cutter, ring cutter, or bone cutter
- Miniature hacksaw
- Saline wash

Variations to the equipment list may be required depending on the location of entrapment and extrication approach.

PATIENT PREPARATION

Explain the procedure and aftercare required to the patient and/or their representative. Obtain appropriate consent to perform the procedure. This includes the type of anesthesia used. The discussion should include risk of neurovascular injury, skin necrosis, and infection, and the potential need for skin excision. Assess the patient's level of anxiety and pain as they must remain calm during the procedure to avoid secondary injury. The application of a topical anesthetic such as EMLA cream may be helpful but delays extraction of the entrapped skin. It has the added benefit of acting as a lubricant. If the patient has significant pain, local anesthetic solution can be subcutaneously infiltrated around the entrapped skin or a penile block (Chapter 156) can be performed. A penile block is preferred over local anesthetic injection into the entrapped skin. A local anesthetic injection will cause increased soft tissue edema

and make removal more challenging. The application of parenteral analgesia, sedation, or procedural sedation (Chapter 159) may be required in rare instances.

TECHNIQUES

MANUAL REMOVAL

Apply mineral oil, surgical lubricant, or viscous lidocaine liberally to the zipper and entrapped skin. Allow the mineral oil to soak the skin and zipper for approximately 10 minutes.^{9,15} Apply gentle but steady traction on the zipper away from the entrapped tissue with special care to avoid further injury.^{9,15} Attempt to dislodge the zipper manually. **Do not forcefully try to unzip it. Excessive force is unnecessary and can result in avulsions and lacerations to the skin.** It may be easier to intentionally close the zipper on the entrapped skin completely then attempt to separate the zipper teeth. If this fails to release the tissue, perform one of the zipper disassembly techniques listed below.

CUTTING THE MEDIAN BAR

This is the method of removal recommended by the majority of authors.^{6,7} Although simple in concept, it can be difficult in practice to cut the median bar as it is often obscured by the entrapped and edematous skin. The median bar is the only component of the mechanism that connects the upper and lower plates. Cutting the median bar should allow separation of the upper and lower plates and extrication of the entrapped skin. A wire cutter may not be readily available in the Emergency Department. It may be beneficial to obtain a wire cutter from the Maintenance Department.

The median bar can be cut with a heavy-duty wire cutter or bone cutter.^{6,7} If the skin is entrapped between the sliding piece and the teeth (Figure 183-2A), carefully cut the median bar (Figure 183-2B). The front and back plates of the zipper will separate and release the entrapped skin (Figure 183-2C). Occasionally, the skin is entrapped between the teeth of the zipper (Figure 183-3). Cut the median bar of the sliding piece to remove the zipper. Manually pull the two rows of teeth apart to release the entrapped skin.

FIGURE 183-2. Cutting the median bar of the zipper. **A.** Skin entrapped between the sliding piece and the teeth. **B.** The median bar is cut. **C.** The front and back plates separate after the median bar is cut and the skin is released.

FIGURE 183-3. Skin entrapped in the zipper teeth. Cut the median bar to remove the zipper and manually separate (arrows) the two rows of teeth to release the entrapped skin.

An entrapment involving a heavy-duty zipper may not be amenable to using a wire cutter. Alternatives to the wire cutter exist. An attempt to cut the median bar may be made with a miniature hacksaw or Dremel tool.¹⁰ **However, this carries a significant inherent risk of secondary injury to the skin or deeper structures.**

CUTTING OF THE CLOTH SURROUNDING ZIPPER TEETH

Occasionally, the skin is trapped between the teeth of the zipper and a wire cutter or bone cutter is not available.⁸ Cut the cloth holding the zipper to the clothes with a bandage or Mayo scissors (Figure 183-4, long dashed lines). Using a small or iris scissors, cut the cloth between the individual teeth that are entrapping the skin (Figure 183-4, small dashed lines). Pull both halves of the zipper apart. Separate the teeth and free the entrapped skin. Extrication may be quicker with this method than cutting the median bar, although location is important.¹² Grasping the cloth and zipper with needle drivers may improve the success rate.¹⁸

This technique is less than ideal. Cutting the cloth between the teeth of the zipper may cause lacerations to the entrapped skin. It is very painful for the patient when the skin is cut. **Exercise great caution when cutting the cloth of the zipper.** Given this risk, some prefer cutting the median bar of the fastener mechanism as described above. It is worth the additional time to locate and borrow a heavy-duty wire cutter from the Maintenance Department to cut the median bar.

CUTTING THE ZIPPER TEETH

Cutting the median bar requires the proper equipment and significant strength. Skin trapped between the teeth of the zipper can be released by cutting across the zipper teeth.⁸ Cut across the closed zipper teeth using a heavy-duty scissors or wire cutter. Pull both

FIGURE 183-4. Skin entrapped in the zipper teeth. Cut the cloth holding the zipper to the clothes (long dashed lines), then cut the cloth between the teeth (short dashed lines).

halves of the zipper apart to release the entrapped skin. Grasping the cloth and zipper with needle drivers may improve the success rate.¹⁸

This method is faster and easier than cutting the median bar if the skin is trapped only in the zipper teeth.¹² There is the risk of secondary injury to the entrapped skin causing an additional laceration or damage to adjacent structures. It may be preferable to make a second attempt at pulling the two sides of the zipper apart prior to cutting the teeth at the level of the entrapment.

PLIERS

Case reports have discussed successful removal of entrapment with the use of pliers.¹⁹ Cut the cloth attached to the zipper as close as possible to the zipper teeth intersection of the zipper. Grasp the proximal end of the mechanism with the pliers ensuring that both the upper and lower plates are grasped. Apply inward force with the pliers to deform the mechanism and release the entrapment. While successes have been reported, care should be taken to first attempt manual removal or cutting the median bar. Failure to achieve release with this technique may result in a deformed sliding mechanism and difficulty in removing the zipper by subsequent methods.

APPLYING LEVERAGE

If the location of the entrapment is firmly within the zipper mechanism and is not amenable to the above methods, a modified and more forcible attempt may be required. This is not ideal as it leaves the entrapped skin vulnerable to secondary laceration or avulsion but may be required for removal. The success of this method is dependent on the durability of the sliding mechanism as a heavy-duty zipper is unlikely to be easily manipulated.

Two techniques are available. A flathead screwdriver or nail lifter may be used to provide leverage to forcibly separate the upper and lower plates.¹³ Insert the flat end in the distal portion of the sliding

mechanism and twist it around its axis clockwise and counterclockwise. This technique uses one plate as a fulcrum to apply pressure. Alternatively, a needle driver may be used to grasp the upper plate while applying upward pressure. If space allows, grasp both the upper and lower plates.²⁰ This may sufficiently bend the median bar to separate the two plates. It is more likely to be used in conjunction with the manual removal technique. With the help of an assistant, one person can provide leverage while the other attempts to unzip the mechanism. **Extreme caution is required, as secondary injury to either provider may occur if leverage is lost or when the mechanism abruptly comes free.**

CUTTING THE FACEPLATE

This technique should only be used as a method of last resort in an attempt to prevent a larger skin excision. Close inspection of the upper plate shows that it is wider at its proximal end and narrows as it tapers to force the two opposing rows of zipper teeth together. If it is impossible to access the median bar and other methods of extraction have failed, an attempt to cut the upper or lower plate at a point where the two rows are not as tightly opposed can be considered with either a ring cutter or Dremel saw.²¹

It is important to note that the circular edge of either device will not cut the flat plate uniformly. Any attempt must be performed slowly and deliberately. The friction caused may heat the metal and puts the underlying skin at risk for secondary thermal injury. Periodic washing with saline to cool the metal zipper may be required. The use of a Dremel tool puts the underlying skin and deeper structures at risk for secondary injury. It is difficult to precisely tell when the circular edge of the Dremel tool passes completely through the plate. To avoid further injury, the entrapped skin should be lifted as far away from deeper structures as possible before cutting.

It may not be necessary to completely cut through the upper plate. Even cutting partially through the plate may decrease its structural integrity and make manipulation possible. Periodically attempt to grasp the upper plate with a needle driver to manipulate the upper plate or use a screwdriver or nail lifter to force the plates apart.

SKIN EXCISION

If all the previously described techniques have failed, a block skin excision may be the only viable removal option. This method should ideally be performed by a Urologist. However, in remote settings or when consultation is otherwise impossible, it may be attempted by the Emergency Physician. The techniques include an elliptical skin excision or circumcision.^{6,15}

ASSESSMENT

Assess the tissue for any signs of injury after the zipper has been removed from the skin. Any open wounds should be cleaned. Apply an antibiotic ointment and gauze bandage over the wound. A Urologist should be consulted for injuries to deeper penile or scrotal structures, if the entrapped tissue is not viable, if there is violation of Buck's fascia of the penis or of the dartos fascia of the scrotum, if the tissue appears infected, or if the laceration is extensive.¹¹

AFTERCARE

Patients with zipper injuries are usually discharged home from the Emergency Department. Their tetanus immune status should be checked and updated if necessary. The patient should be instructed on local wound care and signs of infection. They should return immediately to the Emergency Department if they develop redness, swelling, pus in the wound, or a fever. Otherwise, routine follow-up

within 48 hours to evaluate any wounds or injured tissue is satisfactory for most patients. Although no guidelines or evidence exists, some physicians often prescribe oral antibiotics if there are any abrasions or lacerations to the skin. Nonsteroidal anti-inflammatory drugs can be used to provide analgesia.

COMPLICATIONS

Very few complications are associated with the removal of a zipper. Lacerations to the skin and deeper structures may occur. Secondary soft tissue injury is the most common complication of zipper removal. This may occur due to zipper manipulation through edematous tissue or cutting the skin (with scissors, wire cutter, ring cutter, hacksaw blade, or Dremel tool). Superficial lacerations are commonly associated with cutting of the median bar. Deep lacerations are due to improper positioning of the wire cutter and can be prevented. Superficial lacerations will heal and require no special care. Large superficial lacerations and deep lacerations will require suturing. Hemorrhage is usually self-limiting and can be controlled with application of pressure. Significant or uncontrolled bleeding may indicate involvement of deeper vasculature and require urologic or surgical consultation. Thermal injury in the setting of the Dremel tool use is unlikely but any burns should be treated appropriately. Any secondary injury to deeper structures likely necessitates consultation with a surgical specialist for evaluation. Violation of the skin should be treated with topical and/or systemic antibiotics. Local infections may occur from zipper abrasions, abrasions and lacerations from removal of the zipper, or nonviable and crushed skin. Evidence of infection should always be treated with systemic antibiotics.

SUMMARY

Zipper injuries may occur when opening or closing a zipper. The foreskin, skin of the penis, and scrotum are the structures most commonly entrapped and injured by zippers. Injuries are most common in uncircumcised young boys but can occur in adults with some cognitive or physical impairment. After assessing the degree of injury and the type of entrapment, the zipper should be disengaged from the entrapped tissue. An Emergency Physician should be capable of multiple extrication approaches depending on the location and involvement within the zipper mechanism. Zipper removal is quick, simple, and very satisfying to the patient. Serious complications are unlikely.

Genitourinary Foreign Body Removal

Dennis Hsieh, Claire Lyons, and Karen Lind

INTRODUCTION

The literature is replete with case reports of genitourinary foreign bodies. A 1932 case report of a pencil inserted into the penis describes genitourinary foreign bodies as “not so infrequent.”¹ It is difficult to estimate the incident given the broad variety of anatomic locations and their frequent presence as ancillary complaints to a greater issue (e.g., an assault or psychiatric emergency). A tremendous variety of genitourinary foreign bodies present to the Emergency Department. Genitourinary foreign body insertion is typically iatrogenic, self-inflicted, or traumatic.²⁻⁹ The location of foreign bodies can be categorized by location (e.g., external, subcutaneous, vaginal, and within the urethra or bladder). Foreign bodies that are easily visualized can often be handled in the Emergency Department. Those that are complicated or can only be appreciated by imaging are typically more suitable for removal in the Operating Room.

Polyembolokoilamania is the self-insertion of foreign bodies into various body orifices. It presents in many different populations with a variety of causes that can be grouped broadly.¹⁰ The causes can be further distributed by patient age. These are usually the result of play, trauma, or abuse in children.¹¹ Iatrogenic foreign body retention has been reported.¹¹ Vaginal foreign bodies are common in prepubescent girls for a cause of vaginal bleeding.¹² Investigate all presentations of idiopathic atraumatic vaginal bleeding in prepubescent girls.¹² **Be vigilant for any signs or symptoms of sexual assault. Screen the patient and family as child victims of sexual assault may present with a vaginal foreign body.**¹³ Most presentations in adults are self-insertions due to sexual pleasure, intoxication, or psychiatric conditions.^{14,15} Other causes include penetrating trauma (e.g., bullet in the bladder), erosion or fistulization from adjacent structures (e.g., migrated intrauterine device), accidental (e.g., forgetting to remove a tampon or retained broken condom fragments), sexual assault, or a retained foreign body secondary to smuggling or storing items (e.g., drugs or money) inside the vagina.^{16,17} Women who are victims of sexual assault or who are sex workers may experience vaginal penetration with a foreign body already inside the vagina. This can lead to the object becoming lodged more deeply within the vagina and increase the chance of soft tissue injury.

The presentation of a genitourinary foreign body is often obvious and the patient will openly admit to the issue. The patient may be reluctant to discuss this in triage and may only reveal their concern to the Emergency Physician during the private interview or as an aside at the end of the encounter. Genitourinary foreign bodies must be considered when complaints of dysuria, hematuria, pain (i.e., pelvic, genital, urethral, or lower abdominal), discharge (i.e., penile and vaginal), urinary retention, or urinary tract infection are evaluated as these foreign bodies may present in a delayed fashion or the history may be unreliable. Foreign bodies may present as secondary findings in patients with a presentation of multisystem trauma and assault.

ANATOMY AND PATHOPHYSIOLOGY

The external male genital structures include the penis and scrotum, with the penis serving as a genital and urinary organ (**Figure 184-1**). The external penis includes the penile epithelium, foreskin in uncircumcised males, glans penis, and urethral meatus. The male urethra is approximately 20 cm long. The anterior urethra courses through the urogenital diaphragm and the posterior urethra passes through the prostate en route to the bladder. Intra-urethral foreign bodies may be found at any location within the urethra. Self-inserted foreign bodies are often distal unless the patient uses an instrument to insert the object more proximally. Intraurethral foreign bodies are much less likely to travel into the bladder in male patients due to the length of the urethra, although this has been reported.¹⁸

The vulva comprises the external female genitalia and is composed of the mons pubis, labia majora and minora, urethral meatus, vestibule of the vagina, and vestibular glands (**Figure 184-2**). The vagina is a muscular and cylindrical structure and approximately 9 cm long in the adult patient (**Figure 184-3**).

FIGURE 184-2. The anatomy of the female external genitalia.

The vaginal canal is immediately caudal to the urethra and terminates at the cervix. The uterus is approximately at a 90° angle to the vagina.¹⁹ The female urethra is approximately 4 cm long, located inferior to the clitoris and within the labia minora superior to the vaginal introitus. The urethral meatus in women may be less visible externally in prepubertal and perimenopausal female patients.¹⁹ The urethra may be located more posteriorly in patients with prolapse of the bladder or urethra into the vagina.¹⁹ The route for a foreign body to enter the bladder is short and

FIGURE 184-1. The male genitourinary tract. (Used with permission from www.openstax.org.)

FIGURE 184-3. The female genitourinary tract. (Used with permission from www.openstax.org.)

more direct than in males with less risk of entering an adjacent structure (e.g., the prostate).

Common sites for male genital piercing include the glans penis, penile shaft, scrotum, frenulum, and perineum. Common sites for female genital piercing include the clitoris, labia majora, and labia minora. Subcutaneous genital beads (i.e., pearling) may be implanted by professional piercers or a patient may self-insert an object subcutaneously with or without epithelialization occurring. The Emergency Physician may be tasked with removing these piercings in the case of infection, superficial migration of the piercing (i.e., rejection by the body), or trauma (e.g., tearing or crushing) to the piercing area. These are usually within the purview of the Emergency Physician unless a deep structure is affected or the removal is complicated (e.g., a deformity of the piercing jewelry).

External penile or scrotal foreign bodies may lead to skin erosion, ulceration, and laceration. A very serious complication of external penile foreign bodies is penile incarceration. This may occur with circumferential foreign bodies or those that otherwise entrap distal tissue and place the patient at risk for tissue ischemia with compromised venous return.²⁰

Most internal female genital foreign bodies able to be extracted in the Emergency Department reside within the vagina, cervix, and uterus. **Defer intraperitoneal and intrauterine foreign body management to Surgeons.** Intravaginal foreign bodies may cause trauma. Pressure on the vaginal wall from a retained foreign body may result in edema or erosion with ulceration. A sharp foreign body can cause vaginal or cervical perforation. Lacerations of the vaginal wall or cervix may lead to potentially life-threatening hemorrhage.¹² Visible vaginal wall trauma should prompt an investigation for trauma to adjacent structures (e.g., the bladder, uterus, and rectum). The comparative lack of estrogen in pediatric and postmenopausal patients may contribute to increased vaginal wall erosion from retained foreign bodies.

Foreign bodies retained within the urethra have been associated with urethral stenosis and urinary retention.²¹ Self-inserted foreign bodies may cause posterior urethral injuries with urethral rupture.

This type of injury is more commonly associated with trauma or iatrogenic instrumentation.²² Retained intraurethral foreign bodies can mimic a urinary tract infection or nephritis. Urinary changes (e.g., hematuria, pyuria, and proteinuria) can be caused by urinary tract irritation secondary to a retained foreign body in the absence of infection.^{23,24} Retained foreign bodies much less commonly may present as a nidus for infection in a critically ill patient (e.g., toxic shock syndrome linked to tampon use).²⁵ Prostatitis has been reported as the presenting symptom of a long-term retained foreign body in the prostatic urethra.²⁶ Bladder calculi may form as a reaction to a retained foreign body in the bladder.

INDICATIONS

Subcutaneous foreign bodies may be removed in the Emergency Department if deep structures are not involved. A subcutaneous foreign body purposely inserted for cosmetic or sexual pleasure (e.g., piercing or genital bead) should be removed if it is infected, if the area has been traumatized (e.g., tearing or displacement of the jewelry), or if it is beginning to migrate and cause inflammation. Patients may develop allergies or irritant dermatitis to subcutaneous foreign bodies which is an indication for removal. Delay in removal of problematic subcutaneous foreign bodies increases the likelihood of worsening infection, a poorer cosmetic outcome, or a tissue reaction and makes future removal more challenging.

Retained intraurethral foreign bodies with no medical purpose should be removed when possible in the Emergency Department. Consult a Urologist for more complicated cases. The risk of developing complications (e.g., infection, urethral stenosis, hematuria, pain, urinary retention, or other anatomic disruption) is unacceptably high to leave urethral foreign bodies in place without a plan for removal or observation and close follow-up.

Intravaginal foreign bodies should be removed to prevent them from becoming a nidus for infection. They should be removed if possible without risking significant trauma to the vagina that leads to hemorrhage or vaginal wall perforation.

CONTRAINDICATIONS

Some urethral foreign bodies will be beyond the capacity of the Emergency Physician to remove. A urethral foreign body may present in a location that cannot be reached easily. A urethral foreign body with sharp edges or other characteristics that would increase the likelihood of significant damage with removal should not be removed by the Emergency Physician. Those with evidence of significant surrounding tissue injury or reaction should not be removed by the Emergency Physician. Consult a Urologist in these situations.

Obtain a further workup or consultation prior to attempting removal if the patient presents with evidence of a secondary complication from the foreign body. Vaginal foreign bodies may extend into the peritoneum or into a surrounding organ or can lead to perforation from erosion.^{27,28} These patients may present with peritoneal signs or prolapse of intraabdominal contents. Consult a Gynecologist immediately and further imaging versus immediate operative exploration will be decided in conjunction with the Gynecologist.

Consult a Urologist if the foreign body appears to have caused urinary obstruction, urethral rupture, or bladder perforation.² Obtain advanced imaging unless the consultant wishes to defer imaging and take the patient for surgical exploration. Tissue ischemia (e.g., from penile incarceration) is an indication for emergent consultation with a Urologist.

EQUIPMENT

- Local anesthetic solution
- 25 and 27 gauge needles
- 16 and 18 gauge needles
- 10 mL syringe
- Procedural sedation equipment and supplies (Chapter 159)
- Povidone iodine or chlorhexidine solution
- Personal protective equipment
- Sterile gloves
- #11 blade scalpel
- Hemostat
- Surgical pliers
- Ring forceps
- Tenaculum
- Foley catheter, various sizes
- Anoscope
- Vaginal speculum
- Nasal speculum
- Water-soluble lubricant
- Ring cutter
- Bolt cutter
- Pneumatic saw
- Topical antibiotic ointment
- Bandaging supplies
- Foley catheter and leg bag

PATIENT PREPARATION

The patient must undergo a thorough history and physical examination to determine the overall health of the patient, including a preoperative assessment if appropriate. **Attempt to identify immediately any hemorrhage, vaginal or urethral perforation, and**

new fistulas as these patients need to go to the Operating Room quickly. Consider consulting a Psychiatrist for self-inflicted foreign bodies. **A high suspicion must be maintained for abuse. An appropriate consult (e.g., forensics, social work, or police) must be made when this is suspected or confirmed.**

Determine the type and number of foreign bodies through the work-up (e.g., history, physical examination, and directed imaging). **It is possible to remove the most proximal foreign body and miss others.²⁹ The patient may not be sure of this part of the history and imaging is usually necessary.** An intraurethral foreign body visible through the urethral meatus may have a misleading terminal end and be coiled or kinked in the bladder. This would not be discovered without imaging and attempted removal could be highly traumatic.³⁰ **Plain films are the initial imaging modality of choice. Computed tomography (CT) scans, cystograms, and urethrograms may be required to further characterize the foreign body and the extent of injury.³¹**

It is important to ascertain the technique of the insertion. **Patients with forcefully inserted objects should undergo a trauma-directed work-up. Screen all patients for sexual abuse or assault.** Inquire about the length of time of the insertion. The more edema and mucosal irritation will develop the longer the object is retained. This will make the extraction more difficult and more likely to require procedural sedation (Chapter 159) or removal in the Operating Room.

The parts of the physical examination that are most useful are the genitourinary, abdominal, and rectal examinations. The goal of the abdominal examination is to determine tenderness or signs of peritonitis. Examination of the external male and female genitalia consists of careful examination to determine if the foreign body is exposed, location, size, texture, mobility, and possible areas to grasp. Determining if the object is hard, soft, rubber, plastic, or glass will help determine the appropriate tool for grasping the object. The other consideration is whether the object is sharp or irregularly shaped. A sharp or irregular object can prevent removal or increase the risk of surrounding tissue damage from the removal process.

It is important to note that many patients will present with concern for a retained foreign body (e.g., a woman who is concerned about a retained tampon) and the foreign body may not be present. The vagina is a blind pouch and many women can adequately examine their own vagina for retained foreign bodies. Many women will already have noted they do not feel a tampon but present out of an abundance of concern. Not all women can examine their own vagina completely secondary to habitus, preexisting disease, or psychological reasons. **It is important to examine all patients for a retained foreign body if they report the possibility of one. Reassure the patient that an evaluation by a medical professional is appropriate if they have a concern for a retained object.** Sometimes broken condom fragments can lead to vaginitis that does not improve until the fragment is removed which can be impossible for the patient to visualize and grasp.

Explain the risks, benefits, and alternative procedures to the patient and/or their representative. Inform them that many foreign bodies may be extracted in the Emergency Department. Some will require general anesthesia or surgery. Obtain an informed consent for the procedure and place this in the medical record. When performing the procedure on a neonate or child, it is advisable to give the parent the option to leave the room or look away as the procedure can be disconcerting to some parents. Keep all patients nil per os (NPO; nothing by mouth). Perform a standard preassessment for procedural sedation (Chapter 159) if that will be part of the procedure. Obtain an additional signed consent for anesthesia and any photographs taken.

Reassure all children prior to the physical examination that it is normal for a health care provider to examine their genitals.

Inform them to tell their parents or a teacher immediately if anyone else asks to see or touch their genitals.

Place the patient in the lithotomy position, particularly for intravaginal and subcutaneous female genital foreign body removal. Positioning is otherwise dictated by provider necessity and patient comfort. Many external penile foreign bodies are best removed with the patient supine. Patients undergoing procedural sedation should be supine or in the lithotomy position.

ANESTHESIA

Anesthesia may not be necessary for intravaginal foreign bodies that are not causing discomfort and with a plan for manual or forceps removal. Local anesthesia with regional infiltration of the surrounding soft tissue will likely be sufficient for subcutaneous or external foreign bodies in adults (e.g., piercings and genital beads). Avoid the use of epinephrine-containing agents for local anesthesia of the penis, particularly in patients with peripheral vascular disease. Refer to Chapter 177 for a detailed overview of regional anesthesia for the penis, testicles and epididymis. A pudendal nerve block (Chapter 162) may be used to achieve saddle anesthesia in men and women.

Viscous lidocaine may be used to anesthetize the urethra in the absence of a urethral injury. Avoid viscous lidocaine if there is concern for urethral rupture or further entrapping the foreign body within the urethra. Procedural sedation (Chapter 159) may be a better choice for complete relaxation and amnesia to the procedure in young children. Procedural sedation is an appropriate choice for adults requiring a complicated procedure or one with high risk for injury if the patient is not completely relaxed (e.g., pneumatic saw use to cut through external foreign bodies).

Consult a Gynecologist or Urologist for foreign bodies that fail Emergency Department management. These foreign bodies may require removal under general anesthesia.

TECHNIQUES

There are an infinite variety of objects inserted into the genitourinary system. It is impossible to give specific instructions on how to remove each of them. There are basic general principles that can guide the Emergency Physician. The first is to visualize the foreign body regardless of its location. It is best to abort the removal and proceed to more invasive methods if an intraurethral foreign body is externally visualized or protruding but cannot be removed easily with gentle continuous traction. **Further attempts at removal by traction may cause urethral or bladder damage.** Gentle suprapubic pressure may push the foreign body into the distal vagina. Sometimes a low-lying object may be grasped and removed with gloved fingers, an instrument, or a suction catheter using gentle continuous traction. **It is necessary to do this with direct visualization so that injury will not result.** Grasp metal or plastic objects visualized and low lying with a tenaculum or ring forceps. **Avoid inserting instruments other than a speculum unless the foreign body is visualized. Blind insertion of instruments may push the foreign body more proximally or cause injury.** Do not grasp a sharp foreign body or a foreign body against the vaginal wall blindly as this can cause injury to the vagina upon removal of the instrument. Vaginal foreign bodies may be removed by irrigation to minimize trauma.

PIERCINGS AND SUBCUTANEOUS FOREIGN BODIES

Use hydrogen peroxide or saline to remove any crusting at the site of insertion. The piercing jewelry often can be removed by opening the jewelry as normal if the patient presents with an intact piercing that

is infected. Local or regional anesthesia is usually sufficient if the patient has significant pain. Most body jewelry will open by having one end unscrewed from the base or by opening the ring to allow the captive bead to fall out. A captive bead is held taut inside a jewelry ring to form a closed circle.

Rotate the jewelry until the opening site reached. Clamp a hemostat onto the end if the jewelry has a post with an end that unscrews. Attach the clamp to the shorter end to prevent it from becoming lost in the piercing site. Manually unscrew the other end. Clamp another hemostat on the other end of the jewelry and slowly rotate one hemostat opposite the other if unable to manually separate the ends. The hemostats may be clamped onto the jewelry at whatever angle the jewelry and patient presentation allow. Slow and gentle rotation with reclamping of the hemostats as the rotation continues will open many jewelry pieces and allow for removal.

The jewelry may be opened with surgical pliers if the jewelry is a ring with a captive bead. Open the pliers inside the ring to widen the ring and allow the captive bead to fall out. Alternatively, use one pliers to clamp the ring and a second pliers to manually force the ring open. Stabilize the hands and forearms with both techniques to prevent pulling on the jewelry. Apply firm and slow pressure to minimize traumatizing the site.

Other options do exist. Piercing sites that have become traumatized through ripping, crushing, or other another deformity may require the piercing site to be incised with a scalpel and the piercing removed directly. Attempt to use a ring cutter (Chapter 126) to cut through the jewelry and remove the separate ends.

Subcutaneous foreign bodies may be removed with similar techniques used on nongenital areas of the body if deeper structures are not involved. A genital bead or other item that was specifically designed to be implanted subcutaneously is less likely to have sharp or irregular edges than an object self-inserted by the patient. Removal of these objects has less chance of traumatizing local structures if they have not become displaced. Prepare the skin with chlorhexidine or povidone iodine and allow it to dry. Don sterile gloves.

Make the incision through the skin that has not completely closed over the jewelry with a #11 scalpel blade. Make the incision deeper and longer until the foreign body can be grasped manually, with forceps, or with a hemostat. Remove it with gentle and firm traction. **Stop the traction efforts if the foreign body becomes resistant to removal.** Proceed with further work-up or consult a specialist if there is concern for retained foreign bodies or debris that cannot be removed.

ANAL, SCROTAL, AND PERINEAL FOREIGN BODIES

The techniques for removing rectal foreign bodies are discussed in Chapter 90. Most scrotal and perineal foreign bodies are managed the same way as other subcutaneous or circumferential penile foreign bodies. They may involve entrapment or incarceration of the scrotum and/or testes. Foreign bodies that have involved the testis are much more likely to require a Urologist and potential operative removal with washout. Rectal foreign bodies can perforate the anterior wall and enter the posterior wall of the bladder.^{27,32}

INTRAURETHRAL FOREIGN BODIES

The approach to urethral foreign bodies is determined by the location of the object at the time of presentation and the size of the object (**Figures 184-4, 184-5, and 184-6**). Attempt the extraction of small, mobile, palpable, and externally visualized foreign bodies if the patient has no urinary or abdominal complaints. Determine the

FIGURE 184-4. A radiograph of a fork in the urethra. (Used with permission from Naidu K, et al: An unusual urethral foreign body. *Int J Surg Case Rep* 2013; 4(11):1052-1054.)

extent of the foreign body within the urinary tract before proceeding with removal if it cannot be visualized or palpated, has migrated proximally, or is too friable to be pulled out with external traction. Proceed with imaging.

Visible intraurethral foreign bodies will more likely be amenable to removal from the shorter female urethra. Apply gentle traction manually or with forceps. Items that have migrated to the bladder will require consultation with a Urologist and the use of endoscopy or open cystotomy.¹⁵ Longstanding foreign bodies in the bladder may require lithotripsy prior to removal.^{33,34}

Urethral or bladder foreign bodies (**Figures 184-7 and 184-8**) can be removed several ways. The least traumatic technique is endoscopic removal within the genitourinary tract. This approach can be used for a large range of foreign body shapes and sizes. It is usually performed in the Operating Room under general anesthesia. It can occur in rare instances in the Emergency Department by a Urologist while the Emergency Physician administers procedural sedation (Chapter 159). The foreign body can be pushed retrograde into the bladder to facilitate removal with less trauma to the urethral tract.

More invasive methods when endoscopy fails include open techniques and adjuncts (e.g., open or external urethrotomy with reanastomosis over an indwelling catheter or stent placement). A cystotomy

FIGURE 184-5. A radiograph of an ink pen refill in the penile urethra. (Used with permission from www.medapparatus.com.)

A

B

FIGURE 184-6. A visible intraurethral foreign body. **A.** Forceps grasping the foreign body at the meatus. **B.** Removal of the foreign body. (Photos courtesy of Kevin Binder, PA.)

may be performed for objects that have migrated to the bladder or that were pushed retrograde into the bladder. These patients will be followed by a Urologist as outpatients and may have an increased risk of complications (e.g., urethral stenosis).^{33,34}

FIGURE 184-7. A radiograph of a bobby pin in the bladder. (Used with permission from www.medapparatus.com.)

INTRAURETHRAL FORCEPS REMOVAL

Intraurethral foreign bodies may be removed with forceps if the distal end can be seen and grasped (**Figure 184-6A**). Apply gentle and firm traction to the foreign body until it is removed (**Figure 184-6B**). **Stop the traction efforts if the foreign body becomes resistant or**

FIGURE 184-8. A radiograph of a wire in the bladder. (Used with permission from www.medapparatus.com.)

is too friable to remove intact. Downward traction on the penis may cause the urethra to kink near the penile suspensory ligament. Hold the penis taut when removing intraurethral foreign bodies.¹⁹

VAGINAL FOREIGN BODIES

Vaginal foreign bodies are a common concern for pediatric patients.^{31,35} The patient is often brought in by parents who have noticed a purulent vaginal discharge. A vaginal foreign body in an adult may be the result of sexual practices, psychiatric disorders, or an attempt to avoid law enforcement (i.e., concealment of weapons or drugs).¹⁷ The first step is to visualize the foreign body using a vaginal speculum in the adult. Consider using a nasal speculum in the pediatric patient. **Proceed with imaging and consultation prior to traumatizing an intact hymen.** Determine the location and characteristics of the foreign body. Flush out friable or difficult-to-grab small foreign bodies (e.g., wads of toilet paper or pieces of a broken condom). Use warm water or saline in a syringe or feeding tube. Perform the repeat examination once the material has been flushed out to verify that all foreign bodies have been removed and to identify any mucosal injuries.

A common concern is a lost or forgotten tampon. This can be a nidus for infection and the source of a foul-smelling purulent vaginal discharge. Remove retained tampons with a ring forceps or a tenaculum. Pierce the jaws of the instrument through a finger of a latex glove before using it to remove the foreign body. The glove can be pulled over the removed malodorous foreign body to reduce the odor and be discarded. Irrigate the vagina if unable to visualize the walls easily. Empiric antibiotics may be prescribed or the patient can be reevaluated the following day to determine if the symptoms have resolved. Consider coverage for *Staphylococcus aureus*.³⁶ Antibiotics may not be necessary in the entirely asymptomatic patient who is reliable to return for any worsening conditions.

The female patient should empty her bladder and be placed in stirrups in the lithotomy position to allow visualization. Insert a Foley catheter into the vagina to break the suction between the foreign body and the vaginal mucosa. Grasp the foreign body digitally or with a ring forceps. Remove the foreign body with gentle steady traction. Gentle externally directed pressure (i.e., milking) the walls of the vagina or rectum can facilitate distal movement of the object and its removal prior to the use of forceps or other instrumentation.

Cervical foreign bodies are approached in the same way as vaginal foreign bodies. Removal is most often performed with ring forceps. Proceed with imaging before an attempted removal of the foreign body if there is concern for significant migration into the uterus or uterine perforation. Consult a Gynecologist or Surgeon for any complications.

Most vaginal foreign bodies are usually apparent on speculum examination. Foreign bodies that cannot be visualized in their entirety should be imaged with plain films or CT scans of the pelvis to better characterize the foreign body. Consider procedural sedation (Chapter 159) if the foreign body is easily visualized and is embedded, large, or sharp. General anesthesia may be required to perform a complete examination and facilitate removal under direct vision.

CIRCUMFERENTIAL PENILE FOREIGN BODIES

Penile foreign bodies are common (**Figures 184-9 through 184-13**).^{8,37,38} A penile foreign body in an adult may be the iatrogenic, result from sexual practices, or be due to psychiatric disorders. Techniques first tried may be the same as ring removal (Chapter 126).³⁹ These techniques are often ineffective and more drastic techniques are required.

FIGURE 184-12. Pneumatic saw removal of a circumferential foreign body. (Photo courtesy of Kevin Binder, PA.)

RING OR BOLT CUTTER FOR CIRCUMFERENTIAL PENILE FOREIGN BODIES

A ring cutter or bolt cutter can be used to cut through external circumferential foreign bodies (e.g., a metallic ring) for removal (**Figure 184-11**). A penile nerve block (Chapter 177) supplemented with procedural sedation (Chapter 159) may be used to allow for maximum patient relaxation. **Use care not to damage the underlying tissue.** Cut the foreign body with the ring cutter or bolt cutter. Remove the foreign body manually or with two pliers. A second cut can be made to bisect the foreign body so it falls off the penis and is removed easier.

FIGURE 184-13. Saline cooling of a foreign body during pneumatic saw removal. (Photo courtesy of Graham Brant-Zawadski, MD.)

PNEUMATIC SAW FOR CIRCUMFERENTIAL PENILE FOREIGN BODIES

Circumferential foreign bodies that are too thick to be removed with a ring cutter or bolt cutter can be removed with a pneumatic saw (**Figure 184-12**).³⁷ This equipment is usually not stocked in an Emergency Department. Obtain it from hospital engineering or the fire department. Use procedural sedation (Chapter 159) to obtain maximum patient relaxation and minimize any movement that could lead to inadvertent trauma from the saw. Prepare a bag of normal saline with intravenous tubing attached. Instruct an assistant to control the fluid. The saw will heat the metal. Dripping saline onto the metal will cool it and prevent any smoldering from sparks in the oxygen-rich hospital environment. Have a fire extinguisher in the room for this procedure.

Place protective material (e.g., a section of plastic basin, another thick object, or a reflex hammer blade) above, below, and ideally in between the foreign body and the penis (**Figure 184-13**). This will reduce trauma from saw slippage and sparks. Use the pneumatic saw at a 90° angle to the object and as far away from the patient's skin as possible (**Figure 184-12**). Defer to the Urologist if unable to position the patient adequately to move the skin away and perform the procedure safely. Apply the running saw in 5 to 10 second bursts and check the object in between for temperature. It will likely need to be cooled with saline from the assistant (**Figure 184-13**). Reapply the saw once the object has cooled. Remove the foreign body manually or with two pliers. A second cut can be made to bisect the foreign body so it falls off the penis and is removed easier.

FOLEY CATHETER BALLOONS THAT ARE UNABLE TO BE DEFLATED

Self-retaining Foley balloon catheters are used frequently and typically work well. An indwelling catheter balloon will occasionally not deflate. Most often the problem is a malfunction of the flap-type valve of the catheter's balloon lumen. This valve normally allows fluid to fill the balloon and prevents it from passively leaking out. There are a few ways to deflate the balloon. Target the inflate-deflate channel. Cut off the port and the balloon will often deflate. Insert a needle on a syringe in the inflation channel and suck out the balloon fluid. There is a stepwise series of maneuvers if these are not successful. See Chapter 173 for the complete details of deflating a Foley balloon.

INTRAUTERINE DEVICES (IUDs)

An IUD that causes discomfort or bleeding can be removed in the Emergency Department.⁴⁰ Visualize the string. Firmly grasp the string and pull it gently. **Stop the traction efforts if the IUD is resistant to removal.** It may be embedded in the uterine wall. A Gynecologist must remove the IUD if the string is not visible or gentle traction does not remove the IUD.⁴¹ Discuss the infected or migrated IUD with a Gynecologist before removal.⁴² Obtain an ultrasound or plain film of the abdomen to locate a migrated IUD. Evidence of potential bowel or uterine perforation (e.g., systemic signs of infection or peritoneal signs) requires a CT scan and emergent consultation for potential surgery.¹⁶

A foreign body can enter the uterus (**Figure 184-14**). It is usually placed in the vagina as a result of sexual practices or psychiatric disorders or to avoid law enforcement (i.e., concealment of weapons or drugs). The foreign body starts in the vagina and then migrates into the uterine cavity. Iatrogenic foreign bodies may be left in the uterus after a procedure. Consult a Gynecologist for any foreign body in the uterus.

FIGURE 184-14. A radiograph of a bobby pin deep within the uterus. (Used with permission from www.medapparatus.com.)

BULLETS AND PENETRATING TRAUMA

Bladder perforation must be ruled out for penetrating trauma to the bladder from an object (e.g., a bullet). Delayed migration of a bullet into the urinary tract has been reported from tissue surrounding the bladder or from the renal parenchyma. The foreign body may be removed or the patient managed conservatively if bladder perforation is absent. The foreign body may sometimes exit spontaneously with voiding. Symptomatic foreign bodies (i.e., urinary retention, hematuria, infection, pain, or other symptoms) require endoscopic or cystoscopic removal. An open technique may be required if these approaches fail.^{43,44}

SUPERGLUE OR SILICONE

Superglue or silicone application to the foreskin and distal urethra may be treated under regional anesthesia (Chapter 177). Options include soaking the penis in warm water, application of mineral oil or acetone to break down the glue, and gentle manipulation to avoid more invasive techniques. Viscous substances (e.g., superglue or silicone) inserted transurethrally can cause urethral obstruction from the substance solidifying. Avoid acetone applied inside the urethra as it may cause mucosal irritation.^{45,46} Case reports discuss endoscopic versus external urethrotomy for the removal of the obstructing foreign body.

MAGNETS

One or more magnetic foreign bodies in the urethra or bladder can be removed like any other foreign body.^{29,47,48} The exception to this

is when two magnets trap tissue between them (e.g., one magnet is in the urethra and the other is on the external penis or inside the vagina). Attempt to manually remove the magnets. This may require a penile block (Chapter 177) or procedural sedation (Chapter 159). Consult the appropriate Surgeon if the magnets cannot be separated. Leaving the magnets in place can lead to tissue necrosis and fistula formation.⁴⁹

PEDIATRIC CONSIDERATIONS

Pediatric patients have several special considerations.^{35,48,50} **Maintain a high degree of suspicion for abuse in any young child with a concern for vaginal discharge or foreign body insertion.** Difficulty in obtaining a history compounds this challenge. The Emergency Physician must often rely on symptoms or physical examination findings to diagnose the presence of a foreign body.⁵¹ **Consult Child Protective Services if sexual abuse is suspected.** Provide careful explanations and anticipatory guidance to the child and parents so they understand what will take place.

Case studies have reported 4% to 5% of prepubertal girls with a genital complaint are found to have a vaginal foreign body.³¹ A vaginal foreign body can be the cause of up to 50% of cases of vaginal bleeding and 18% of cases of vaginal discharge in prepubertal girls.³¹ Test all prepubertal girls with vaginal foreign bodies for sexually transmitted infections to rule out sexual abuse. These symptoms will often present in a delayed fashion.⁵²

Place pediatric patients in the knee-chest position (Figure 88-5). Rectal and abdominal examination may identify a foreign body. The foreign body may be expelled from the vagina by pushing with the examining finger in the rectum. Friable foreign bodies (e.g., wads of toilet paper) can be irrigated out using warm water and a standard syringe or infant feeding tube. Removal can also be performed using forceps or a cotton tip swab. A nasal or otoscope speculum can be used for smaller pediatric patients to directly visualize a foreign body and assess for signs of vaginal trauma.^{13,51} Consider examination and removal under general anesthesia if there is a concern for a sharp object or if the above techniques fail.

Dysuria, urethral bleeding, and urethral discharge can be signs of male foreign bodies. As with female patients, these symptoms can be delayed for months or years.⁵³ A complete examination includes palpating the penis for masses and close examination of the urethral meatus. Endoscopic examination and/or surgical removal of foreign bodies may be necessary.

AFTERCARE

Update the patient's tetanus vaccination if there is a skin break secondary to the foreign body or the removal technique. Prescribe oral antistaphylococcal antibiotics if there is an infection or if removal has led to significant trauma to the urethra, deep structures, or adjacent organs (e.g., the cervix).

Inspect the skin of the penis for any erosions or lacerations after removal of circumferential penile foreign bodies (Figure 184-15). Any erosions or lacerations require wound care. The penis may remain quite engorged for some time. Carefully evaluate all areas that may be hidden within folds of tissue. Treat erosions and abrasions to the skin with antibacterial ointment. Instruct the patient to monitor the area for the signs associated with the development of an infection. Discharge patients requiring a skin incision to remove a subcutaneous foreign body with wound care to include topical antibiotic cream, bandaging supplies for the first 24 hours, a scheduled wound check, and return precautions. Antibiotics do not need to be prescribed for piercing or subcutaneous foreign body removal if there is no preexisting infection and deep structures are not involved.

FIGURE 184-15. Penile erosions from a foreign body. (Photo courtesy of Kevin Binder, PA.)

The patient should demonstrate the ability to urinate freely prior to discharge following removal of an intraurethral foreign body. Insert a Foley catheter after the removal of the foreign body to prevent urinary retention and stricture development if there is evidence of intraurethral trauma (e.g., blood, significant pain, or removal of tissue with the foreign body). An intravaginal or external foreign body with significant associated tissue swelling is an indication for a Foley catheter to prevent development of urinary retention. Apply a leg bag and teach the patient and/or their representative to empty the bag. Arrange follow-up with a Urologist for further management and Foley catheter removal.

Advise the patient to allow the site to heal without replacing the foreign body and to avoid repiercing the area if a purposely inserted subcutaneous foreign body (e.g., a piercing or genital bead) is removed. This is especially true if keloid development had complicated the initial piercing. Counsel the patient to avoid using that specific material elsewhere on their body if they have a dermatitis or other allergic reaction to the foreign body.

COMPLICATIONS

Trauma to the urethra may have similar consequences to trauma caused by the foreign body itself (e.g., infection, diverticula, false tracts, bladder perforation, fistula, and urethral tears) and lead to urethral stenosis.²⁸ **Document any associated complication from the foreign body prior to attempting its removal.** Any trauma can result in urinary retention or stenosis and necessitates the insertion of a Foley catheter.

FUTURE CONSIDERATIONS

The Emergency Physician may eventually use limited endoscopy to remove a urethral or bladder foreign body. This is analogous to the use of bronchoscopes. One system is the Isiris (Coloplast Group, Denmark).⁵⁴ This is a single-use cystoscope that connects to a portable monitor (Figure 184-16A). The cystoscope has a lens on the tip of the catheter and a built-in grasper. The handle has simple fingertip controls for catheter tip deflection and the grasper. The monitor can record for teaching and the medical record. A wide variety of foreign bodies can be removed (Figure 184-16B).

SUMMARY

Genitourinary foreign bodies are a common reason for presentation to the Emergency Department. Take a thorough history in patients who present with this as a chief complaint and those who present

A

B

FIGURE 184-16. The Isiris endoscopy system. **A.** The system. (Photo courtesy of Coloplast Group.) **B.** Foreign bodies removed with the Isiris. (Used with permission from reference 54.)

with symptoms that may be secondary to an underlying retained foreign body. Always consider abuse. Suspected foreign bodies or those that are not visible should be investigated with imaging (e.g., plain radiographs, ultrasound, and CT). There are a variety of removal tools and techniques in the Emergency Physician's arsenal. The indications for removal in the Operating Room include proximal location (e.g., uterus, bladder, or proximal urethra), significant associated illness or injury, or high risk for complications. Most patients not requiring surgical treatment may be discharged home from the Emergency Department. Observation is warranted in certain patients for the development of significant complications.

Eye Examination

Shari Schabowski and Carmen Alcala

INTRODUCTION

Emergency Physicians often approach the eye examination with apprehension. Eye complaints compose up to 10% of Emergency Department (ED) visits. **A systematic approach to the eye examination can alleviate any discomfort and provide the basis for an accurate diagnosis and treatment.**¹⁻¹⁴ The most common ophthalmologic problems that present to an ED are infection, inflammation, injury, and visual disturbances.

A careful history will help guide the differential diagnosis and the physical examination. It must include a history of the presenting complaint, the mechanism of any injury, exposures to chemicals or infectious agents, baseline visual acuity, known ophthalmologic problems, baseline medical problems, current medications, and any known allergies. **The eye examination progresses from the outside and works inward beginning with the visual acuity to assess the function of the eye. It is important to routinely inspect all anatomic structures of the eye regardless of the presenting eye complaint. Secondary problems (e.g., corneal lesions associated with conjunctivitis) may be missed if a complete and systemic examination is not performed on all patients.**

EYE ANATOMY

The bony orbit is pyramidal in shape, surrounds the eye, and surrounds the associated neurovascular structures. The blood supply to the structures of the orbit originates from the ophthalmic artery. The anatomy of the eye and its surrounding soft tissue structures is demonstrated in **Figure 185-1**. A detailed discussion of the complex anatomy of the eye is beyond the scope of this chapter. The anatomy relevant to the eye examination will be discussed throughout this chapter.

VISUAL ACUITY

Visual acuity is referred to as the vital sign of the eyes. It provides a means for the functional assessment of this delicate sensory apparatus. **Documentation of the visual acuity is essential when approaching a patient with eye complaints.** Assess the patient's visual acuity as soon as possible, preferably as part of the triage assessment, but at least as the primary assessment during physical exam. There are few exceptions to this rule. Chemical exposures to the eye require immediate irrigation to avoid potentially irreversible visual loss. **Do not delay irrigation for visual acuity testing. Failure to document visual acuity is a common omission, may limit the differential diagnosis, and may have medicolegal ramifications.**

Always test each eye individually and then both simultaneously. Test and document the visual acuity with the respective annotation to the right eye (OD), the left eye (OS), and both eyes (OU). Test the problematic eye first. Completely cover the eye not being tested.

Light shining into the opposite eye may adversely affect the results of visual acuity testing. A list of commonly used abbreviations in the measurement of visual acuity is provided in **Table 185-1**. Inquire as to the patient's baseline visual acuity and whether they wear corrective lenses for reference. Test the visual acuity using corrective lenses (CC) whenever possible (SC indicates without correction). Consider the use of a pinhole device to help correct any refractory errors when corrective lens are unavailable (**Figure 185-2**).

Use caution when allowing contact lenses to be used as a visual aid in patients with eye pain, an eye injury, or an eye discharge. Their application may worsen the ocular condition. **Remove all contact lenses before the slit lamp examination and fluorescein staining. Fluorescein will permanently stain soft contact lenses and may stain hard contact lenses.**

An accurate assessment of visual acuity is essential and this cannot be overemphasized. It is not uncommon to miss a secondary ophthalmologic diagnosis when there is no recognition of a change in visual acuity. **A patient with previously normal (20/20) vision with or without correction that has an acute deterioration to 20/50 or more suggests a serious ophthalmologic condition.** These cases require emergent consultation and prompt referral to an Ophthalmologist.

VISUAL ACUITY CHARTS

The Snellen eye chart is the most commonly used tool for assessing visual acuity (**Figure 185-3**). Place the Snellen chart on a flat wall in a well-lit room without obstructions. Place the patient standing 20 feet from the chart. Instruct the patient to read each line of the chart beginning at the top and proceeding to the bottom or until they are unable to correctly and consistently read the letters with one eye completely covered. **The visual acuity is the fraction corresponding to the last line for which the patient identifies at least half of the letters correctly (i.e., 20/40).** The numerator corresponds to what the patient can see at 20 feet. The denominator corresponds to the distance where a patient with normal vision would be able to read the same line accurately. For example, a patient with a visual acuity of 20/40 sees at 20 feet what a patient with normal vision would see at 40 feet. Document the fraction corresponding to the line minus the number of letters missed if the patient accurately identifies more than half of the letters on that line (e.g., 20/40 -3).

Move the patient closer and reevaluate the visual acuity when a patient is unable to read the Snellen chart at 20 feet. Test the patient 10 feet from the chart. The test is the same at 10 feet as it is at 20 feet and the documentation changes. Recall that the numerator corresponds to the patient's distance from the chart. Document 10/200 if starting at the 10 foot mark and the patient is able to read the letter at the line designated 20/200. The test can also be performed at 5 feet or closer with the appropriate change in the numerator.

The Snellen chart has historically been the most effective and readily available tool for documenting an accurate and reproducible visual acuity in the ED. The Early Treatment Diabetic Retinopathy Study (ETDRS) chart is more frequently used for optimal accuracy and research purposes (**Figure 185-4**). It is replacing the Snellen

FIGURE 185-1. Anatomy of the eye and its surrounding soft tissues. **A.** Surface anatomy. **B.** Midsagittal section through the eye.

TABLE 185-1 Commonly Used Abbreviations for the Documentation of Visual Acuity	
CC	with correction

—	negative

charts. There are circumstances when these charts are less effective. These charts use the English alphabet and effective use requires that the patient can identify all letters. This is difficult, if not impossible, in patients who are illiterate or do not speak and/or read English. The illiterate E chart is an alternative (**Figure 185-5**). Instruct the patient to identify the direction that each “E” is facing. Another alternative is to use a pediatric visual acuity chart (**Figure 185-6**). Instruct the patient to identify the objects on each line. These visual acuity charts are assessed and documented like that of the Snellen chart.

There are a few circumstances where the standard eye chart may give falsely low and inaccurate readings. Patients with eye pain or photophobia may have difficulty reading the chart in bright light secondary to excessive blepharospasm, lacrimation, or pain. There are several options to provide a more optimal assessment of visual

FIGURE 185-2. Pinhole devices. **A.** Black multi-pinhole occluder. **B.** Lorgnette 17 pinhole occluder.

FIGURE 185-3. The Snellen eye chart.

acuity in this situation. A Rosenbaum card is the hand-held equivalent of the Snellen chart (Figure 185-7). It is viewed at 14 inches. Its advantages are that it can be used in the patient’s room with less offensive lighting and can adjust for refractory errors in near-sighted patients who present without correction. A clever idea that some use is to attach a 14 inch string or suture to the Rosenbaum card so that it can be accurately tested at the exact distance each time. A near vision test for children may be used to assess visual acuity (Figure 185-8). Online versions are available for tablets and phones when standard charts are not available.

Photophobia or eye pain (e.g., from corneal injuries or lesions) may prevent the patient from complying with the visual examination. They may often have difficulty opening their eye. The instillation of a topical ophthalmic anesthetic agent may be remarkably helpful as an adjunct to the visual acuity evaluation and the remainder of the eye examination.

FIGURE 185-4. The Early Treatment Diabetic Retinopathy Study (ETDRS) chart.

FIGURE 185-5. The illiterate E chart.

PINHOLE DEVICE

The pinhole device can filter out excessive light (Figure 185-2). It allows direct light rays to pass through the holes while blocking divergent light rays. This results in a sharper, but dimmer, image on the retina. The pinhole device may correct refractory errors to 20/30. An index card punctured multiple times with an 18 gauge needle can substitute if the pinhole device is not available. Use the pinhole device in a well-lit room because it results in a dimmer image on the retina. Instruct the patient to place the pinhole device over the eye being tested and close the other eye. Make a notation in the record that the pinhole device (PH) was used in the measurement of the visual acuity.

FINGER COUNTING

Another means of visual acuity assessment must be used if the patient is unable to identify the letter or object in the 20/200 position, the first and largest letter in the Snellen visual acuity chart. The

FIGURE 185-6. The pediatric visual acuity chart.

next level of visual acuity that is traditionally accepted is the ability to count fingers (CF). It is important for documentation that the record notes at what distance from the eye the patient consistently counted the examiner's fingers (e.g., OD CF at 12 inches). **The distance used for counting fingers is the distance where the patient is first able to accurately complete the test.** Test one eye at a time and then both eyes simultaneously.

Documentation of "CF at 2 feet" means that the patient can accurately count fingers starting at 2 feet. This implies that the patient cannot accurately count fingers if they were held at a distance greater than 2 feet. It is very important to determine the distance where the patient can accurately count fingers and measure this distance with a tape measure. **Do not estimate the distance.**

HAND MOVEMENTS

The next test of visual acuity to perform is hand movements if the patient cannot count fingers. Move or wave a hand back and forth in front of the eye being examined. Document hand movement positive (HM+) or hand movement negative (HM-). Note the distance from the eye that hand movement is first visible (i.e., how close to the eye must the hand be positioned) in the medical record (e.g., HM+ at 12 inches). Test one eye at a time and then both eyes simultaneously.

LIGHT PERCEPTION

The next determination of visual acuity is light perception if the patient is unable to perceive hand movement. Use a penlight or

FIGURE 185-7. The Rosenbaum pocket vision screener.

ophthalmoscope to determine the presence or absence of light perception. Shine the light directly into one eye while the opposite eye is covered. Document the patient's ability to correctly identify when the light is on and off. This is noted as light perception positive (LP+) or light perception negative (LP-). Test one eye at a time and then both eyes simultaneously. **True blindness is present when the patient has no light perception.**

UNCOOPERATIVE OR UNRESPONSIVE PATIENTS

Unresponsive patients are a challenge for the evaluation of visual acuity. Shine a light into each of the patient's eyes to test for pupillary reactivity. Move the light slowly through the cardinal positions to identify if the patient tracks the light movement. Refer to the evaluation of extraocular movements section below. Perform the doll's eyes maneuver if the patient is unable to track the light (Chapter 151).
A difficult situation occurs in the patient whose visual acuity is "no light perception or LP-" but has normal pupillary responses and normal responses to the doll's eyes maneuver. This suggests that the visual loss is psychological and not anatomic or physiologic. Test the optokinetic reflex using a spinning device or a scintoscope to narrow the differential diagnosis. A patient who can see movement will not be able to resist the normal tracking response to the rotating cylinder. A positive response will appear as nystagmus upon examination.

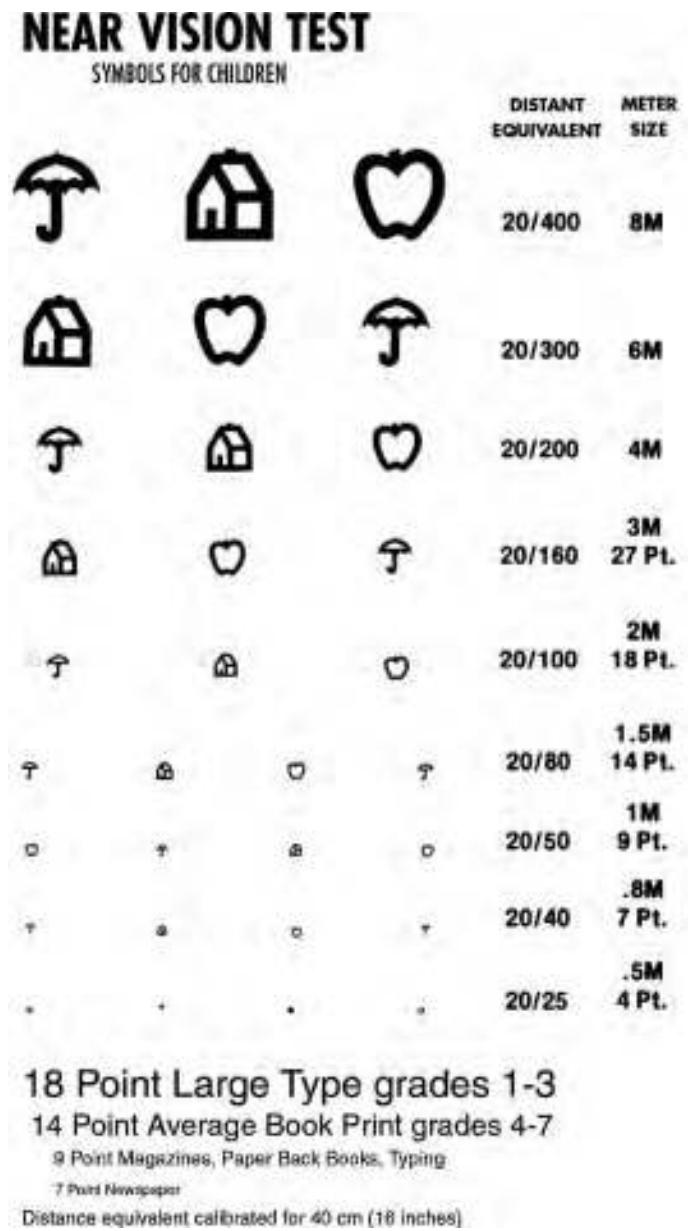

FIGURE 185-8. The near vision visual acuity test uses symbols for children.

PEDIATRIC VISUAL ACUITY TESTING

It is important to evaluate the vision of infants. There is a critical time during which visual problems must be corrected to avoid permanent visual disturbances. This is optimally before 4 months of age. The eyes continue to develop quickly up to 2 years of age. Refer any questionable visual disturbances to a Pediatric Ophthalmologist.
Infants from term delivery to 4 months of age are not able to consistently follow and track objects. An infant's eyes may not move in perfect alignment until the age of approximately 4 months. Infants begin to focus on faces and follow them at approximately 6 weeks of age. They should consistently focus on objects and follow objects at 4 months of age.
Testing an infant's vision can be quite difficult. Place the infant with their parent holding them in the feeding position. Cover one of the infant's eyes. Ask the parent to move their head from side to side. Note whether the infant's uncovered eye tracks the parent's face. Repeat this with the opposite eye covered. The inability to track objects suggests that the visual acuity is 20/200 or worse.

FIGURE 185-9. The Allen chart to measure pediatric visual acuity.

Children who cannot yet read or identify the letters of the alphabet are at a disadvantage when using the Snellen chart (Figure 185-3). Use the illiterate E chart (Figure 185-5), the pediatric visual acuity chart (Figure 185-6), the pediatric near vision test (Figure 185-8), or the Allen chart (Figure 185-9) to test their visual acuity. The illiterate E chart requires the patient to identify the direction that each variably rotated letter “E” faces (i.e., up, down, right, and left). Some clinicians find it helpful to describe the “E” as a table and ask which way the legs are facing. The pediatric charts use shapes of common objects in the place of letters and apply the same corresponding fractions for determining visual acuity. Have the child identify each of the pictures before beginning the examination to ensure that the child knows what the picture represents. Children may use unexpected words to identify the objects which may complicate the interpretation of the exam.

GENERAL INSPECTION OF THE EYE

The examination of the eye proceeds from the outside and works inward. Begin with inspecting the external structures. Note the presence of any enophthalmos or exophthalmos. This is best accomplished by viewing the eyes from above and behind the patient. The normal globe position is just within the orbital rim. Enophthalmos is a recession of the globe within the bony orbit. It is an important clue for the presence of a blow-out or orbital floor fracture (Figure 185-10).¹⁵ Exophthalmos is a protrusion of the globe from the bony orbit. It may be an important clue to the presence of a retrobulbar hemorrhage (Chapter 194) or an orbital cellulitis.

A

B

FIGURE 185-10. Right orbital floor fracture or blow-out fracture. **A.** Entrapment of the right eye limits upward gaze. **B.** A computed tomography image of the fracture (arrow). (Photos used with permission from reference 15.)

Esotropia is a form of strabismus that refers to an inward or nasal deviation of the globe (Figure 185-11). Exotropia refers to a form of strabismus that has an outward or temporal deviation of the globe (Figure 185-11).

Evaluate the eyes and eyelids for discoloration, lesions, eyelid position, obvious injuries, swelling, and/or symmetry. Ptosis suggests a Horner's syndrome or a third cranial nerve abnormality. **Any evidence of facial trauma or eye trauma raises the possibility of a ruptured globe. Avoid placing pressure directly on the globe if there is any possibility of a ruptured globe.** Inadvertent tactile pressure placed on a ruptured globe may result in extrusion of intraocular structures. This can result in an otherwise avoidable visual loss that is typically not repairable. Manipulate the eyelids by applying pressure over the bony orbit instead of directly on the globe (Figure 185-12).

FIGURE 185-11. Types of strabismus.

EVALUATION OF EXTRAOCULAR MOVEMENTS

Extraocular movements are easily assessed in the cooperative patient. Instruct the patient to keep their head still and directed toward the examiner. Instruct the patient to follow the motions of a finger with only their eyes as it follows the pattern of an “H” (Figure 185-13). This is referred to as the six cardinal positions for testing extraocular muscle movements. It may be helpful to retract the patient’s eyelids to better visualize the eye movements. Observe the eyes for symmetric or conjugate gaze as each position is reached.

FIGURE 185-12. Open and close the eyelids by applying pressure over the bony orbit in suspected cases of a ruptured globe.

Note whether the patient sees one finger clearly at each position. Ask the patient to describe the orientation of the images (e.g., side to side) if more than one image is noted. Assess the far lateral positions by paying careful attention for evidence of nystagmus. A few beats of nystagmus that quickly extinguish are within normal limits. Keep in mind that the nose may obstruct the view at extreme points. Move the examining hand into a plane that is a few inches closer to the Emergency Physician if this occurs (i.e., a few inches away from the patient) and repeat the testing.

It is helpful to use a penlight directed toward the patient’s eyes during the examination when a question of subtle disconjugate gaze is entertained, particularly in the position where the patient complains of diplopia. Look at the patient’s pupils to see the reflection of the light (Figure 185-14). The reflection of the light is symmetrical and located in the same position in each pupil if the gaze is conjugate (Figure 185-14A). Asymmetrical light reflection is noted in cases of disconjugate gaze (Figure 185-14B).

Consider the innervation of the extraocular muscles to narrow the differential diagnosis when abnormal extraocular movements are identified. The lateral rectus muscle is innervated by the sixth cranial nerve (CN VI). The superior oblique muscle is innervated by the fourth cranial nerve (CN IV). The remaining extraocular muscles are innervated by the third cranial nerve (CN III). **An isolated sixth cranial nerve palsy, particularly in a child, strongly suggests an intracranial neoplasm. A complete third cranial nerve palsy suggests an intracranial aneurysm pressing on the oculomotor nerve, particularly when the pupil is involved.** A physical obstruction originating in the retrobulbar region manifests as restricted extraocular movements in one eye. Consider the presence of an orbital cellulitis or a retrobulbar hemorrhage in the appropriate clinical setting.

Consider the presence of an orbital floor or blow-out fracture if the patient is unable to elevate one of the eyes (Figure 185-10). The

FIGURE 185-13. The six cardinal positions for testing extraocular muscle movements. Start with the eye facing forward and follow the order of the numbers following an H shape.

FIGURE 185-14. Shine a penlight into the eyes in the position that the patient complains of diplopia and observe the light reflection in the pupils. **A.** Conjugate gaze. **B.** Disconjugate gaze.

etiology of the restricted movement may be physical entrapment of the inferior rectus and/or inferior oblique muscles within the orbital floor fracture or a contusion of the nerve innervating the inferior oblique muscle. The two must be distinguished as the management, treatment, and follow-up are different. Place two drops of a topical ophthalmic anesthetic agent into the affected eye. **Gently grasp the bulbar conjunctiva with forceps and attempt to gently elevate the eye.** An entrapment is ruled out if the eye is elevated and a nerve contusion is more likely.

EXAMINATION OF THE PUPILS

Place the patient with their head looking directly forward while retracting the upper eyelid. Complete the pupillary examination and a cursory evaluation of the cornea and anterior chamber simultaneously. Clinicians commonly use the abbreviation “PERRL” as documentation for the pupillary examination. “PERRL” means the pupils are equal, round, and reactive to light. Disorders of accommodation rarely contribute to any ED diagnosis and it is not routinely tested. **Be sure that you assess accommodation if you use the acronym “PERRLA.”** The abbreviation “PERRL” is typically inadequate when a patient has emergent eye complaints.

Document a detailed pupillary exam. Darken the room as much as possible. Instruct the patient to focus on a distant object. The normal response is symmetric dilation of the pupils. Note the size, in millimeters, of each pupil. Shine a focused beam of light into one eye to test reactivity or the direct pupillary response to light. The normal pupil will constrict immediately and briskly. Document the direct response to light in millimeters at the maximal constriction (e.g., OD = 4 mm → 2 mm). Note if the pupil is not briskly reactive (e.g., OS = 5 mm → 3 mm, sluggish) or if it dilates (e.g., OS = 3 mm → 6 mm). Repeat this test with the contralateral eye. There are handheld devices that can provide extremely accurate pupillary size and reactivity measurements but this is rarely necessary outside of the Intensive Care Unit.

The consensual pupillary response is the reaction of the contralateral eye to light shined into the opposite eye. The normal consensual pupillary response is constriction of the contralateral pupil when light is shined into the opposite eye. This occurs because some of the efferent optic nerve fibers cross the midbrain to the contralateral optic tract and result in constriction of the contralateral pupil. Be careful to document a normal consensual response if it is present.

The consensual pupillary response can be used as a diagnostic tool when assessing an inflamed eye. Close and cover the affected

eye and shine the light in the opposite eye. Pain associated with the consensual pupillary response in the covered affected eye suggests deep inflammation or an uveitis.

A common example of an abnormal pupillary examination illustrates the importance of paying specific attention to the consensual pupillary response. The relative afferent pupillary defect (RAPD) results from the tested eye not perceiving the light. There is no perception of light (i.e., LP–) transmitted to the optic tracts. The tested pupil will not constrict to direct light. The pupil may inappropriately dilate in response to direct light. There will be no consensual response in the contralateral pupil. The contralateral pupil will constrict appropriately to direct light and the previously unresponsive pupil will demonstrate a normal consensual response. The “swinging flashlight test” is used to test for a RAPD. Shine the light into one eye. Note the direct and consensual responses. Swing the light over to test the opposite eye. Note the direct and consensual responses of each eye.

A common problem is the patient with unequal pupils. The primary consideration is typically a “blown pupil” suggesting an uncal brain herniation from a mass lesion. This would be very unusual in a patient who is awake, alert, and cooperating with the eye examination. A physiologic anisocoria is the most common cause. Patients with physiologic anisocoria will have a normal response to light and typically the difference in pupillary size will be no more than 2 to 3 mm. **Determine which of the two pupils is problematic if the response is abnormal.** The normal response to a darkened room is dilation. The pupil that does not dilate is abnormally miotic. The appropriate response to bright light is constriction. The pupil that does not constrict is abnormally mydriatic.

It is important to note and document the shape of each pupil as they should be round and regular. Irregularly shaped pupils may give important clues to undiagnosed injuries. A D-shaped pupil suggests a disruption of the ciliary muscles in the region adjacent to the flat part of the “D.” A teardrop-shaped pupil suggests a ruptured globe with the point of the teardrop directed toward the point of penetration. A quivering and dilated pupil that does not react appropriately to light suggests a lens dislocation partially obstructing the visual axis. An irregularly shaped pupil may be an important diagnostic clue but do not be misled. The most common cause of an irregularly shaped pupil is a postoperative change. **Always inquire about previous eye surgery or old injuries, especially if an abnormality is noted.**

Perform a cursory evaluation of the cornea and anterior chamber simultaneously. Look at the shape and note any foreign bodies present. Look for the presence of a hyphema (**Figure 185-15**). This is blood in the anterior chamber. A small amount of blood

FIGURE 185-15. A hyphema. (Used with permission from reference 15.)

FIGURE 185-16. A foreign body embedded under the upper eyelid. (Used with permission from reference 16.)

may only be seen with the assistance of gravity when the patient is upright.

The NeuroOptics NPi-100 pupillometer (NeuroOptics, Irvine, CA) has been developed to accurately measure pupil size and reactivity. This hand-held device is easy to use, takes over 30 pictures a second, analyzes the pictures, and prints via infrared to a portable printer. It can display values over time numerically or graphically. It is not for routine daily use in the ED. It has a role in the evaluation of critically ill or injured patients.

EXAMINATION OF THE EXTERNAL STRUCTURES

The examination should proceed from the outside and work inward following an anatomic checklist. Examine the eyelids, lash line, and tarsal plates. Examine them for infection, inflammation, injury, normal position of the eyelashes, and symmetry. Examine the puncta of the lacrimal apparatus for signs of inflammation and obstruction. Examine the bulbar conjunctiva and vasculature for chemosis, ciliary flush, discharge, foreign bodies, and injection. Examine the cornea for clarity, evidence of injury, foreign bodies, or lesions. Examine the palpebral conjunctiva and cul-de-sac for discharge, foreign bodies, injection, and lymphatic (i.e., follicular) enlargement. Examine the anterior chamber for clarity, depth, and particulate matter.

Expose the structures of the inner aspect of the upper eyelid to look for a foreign body (**Figure 185-16**).¹⁶ Evert the eyelids

FIGURE 185-18. Eversion of the lower eyelid.

(**Figures 185-17 and 185-18**) or retract the eyelids (**Figures 185-19 and 185-20**). Place the patient facing forward with their eyes focused downward to evert the upper eyelid (**Figure 185-17**). **The patient's eyes must remain directed downward during the entirety of the examination as looking up or forward will cause the eyelids to return to their natural position.** This process requires the use of a cotton-tipped applicator. An assistant may be required to aim and focus a light source during the examination if it requires two hands to evert and hold the eyelids in position.

Grasp the midpoint of the upper eyelash line or the tarsal plate between the index finger and thumb (**Figure 185-17A**). Place a cotton-tipped applicator 0.5 to 1.0 cm superior to the tarsal plate with the cotton tip in the midplane of the upper eyelid (**Figure 185-17A**). Apply gentle pressure directed slightly downward against the upper eyelid with the cotton-tipped applicator. Use the other hand to pull the eyelid upward and evert it (**Figure 185-17B**). The upper eyelid may not completely evert. Sweep the cotton-tipped applicator from left to right while still holding the lash line in one hand and simultaneously applying gentle downward pressure with the

FIGURE 185-17. Eversion of the upper eyelid. **A.** Grasp and pull down the upper eyelashes while simultaneously placing a cotton-tipped applicator at the base of the upper eyelid. **B.** Flip the upper eyelid over the cotton-tipped applicator. **C.** Hold the everted eyelid in place and gently remove the cotton-tipped applicator.

FIGURE 185-19. Eversion of the upper eyelid with a Desmarres retractor. **A.** Place the retractor 5 mm above the tarsal plate. **B.** Grasp the eyelashes and evert the upper eyelid over the retractor. **C.** Elevate the retractor to fully expose the under surface of the eyelid.

applicator within the false pocket to completely evert the upper eyelid (**Figure 185-17C**). Gently and slowly remove the cotton-tipped applicator.

Eversion of the lower eyelid is much simpler (**Figure 185-18**). Instruct the patient to look upward. Place the index finger on the patient's lower eyelid. Apply downward traction to evert the lower eyelid.

The use of a Desmarres eyelid retractor is an alternative option to retract the eyelids. It is very difficult to manually evert the eyelids when they are swollen. Manual eyelid eversion can result in excessive pressure being placed on the potentially injured globe. An eyelid retractor can be used to avoid placing pressure on the globe (**Figure 185-19**). Place the patient facing forward with their eyes directed downward. Place the eyelid retractor approximately 5 mm above the tarsal plate on the outer surface of the eyelid (**Figure 185-19A**). Grasp the midpoint of the upper eyelash line or the tarsal plate between the index finger and thumb. Slightly retract the upper eyelid away from the globe. Elevate and retract the tarsal plate upward to evert the eyelid onto the retractor (**Figure 185-19B**). Lift the retractor upward to fully expose the undersurface of the eyelid (**Figure 185-19C**).

This technique allows the eyelid to be retracted with one hand while directing the light with the other hand. It prevents any pressure from being placed on the globe if a rupture is suspected. It may be necessary to slide the retractor 0.5 cm to the left and to the right of midline to fully visualize the ocular structures. Use the same technique to retract the lower eyelids. Instruct the patient to direct their gaze and focus upward when retracting the lower eyelid.

The eyelids can be retracted but not everted with the Desmarres retractor (**Figure 185-20**). Place the eyelid retractor in front of the upper eyelid (**Figure 185-20A**). Gently insert the retractor under the upper eyelid (**Figure 185-20B**). Apply slight outward traction on the retractor to securely grasp the tarsal plate. Rotate the retractor upward to retract the upper eyelid (**Figure 185-20B**). Elevate the retractor upward to open the eyelid (**Figure 185-20C**). Use the same technique to retract the lower eyelid. **Never use this technique if a foreign body or ruptured globe is suspected.** It may cause secondary injury by embedding a foreign body, perforating the globe with the foreign body, or causing extrusion of the ocular contents if the globe is ruptured.

Lid retractors should be a part of an ED eye kit (**Table 185-2**). If a retractor is unavailable but it is necessary to retract a swollen lid, a paper clip can be configured into a retractor (**Figure 185-21**).¹⁷ Take care to inspect the quality of the metal surface of the paper clip. It is possible that the metal could flake off and cause an eye injury. Plastic-coated paper clips might be a safer alternative to metal paper clips.

SLIT LAMP EXAMINATION

The slit lamp is essential for a thorough eye examination (**Figure 185-22**). It is an invaluable resource that can be used to identify and aid in the treatment of ophthalmologic problems that might otherwise go unrecognized. It provides an adjustable light source with variable magnification. The eyes remain in a fixed position while the light and microscope are independently adjusted. The result of these attributes is that it can focus precisely on the

FIGURE 185-20. Retraction of the upper eyelid with a Desmarres retractor. **A.** Place the retractor in front of the eyelid. **B.** Insert the retractor and rotate it toward the forehead. **C.** Elevate the retractor to fully expose the globe.

Topical mydriatic agents (e.g., phenylephrine)
Topical pupillary constrictors, (e.g., pilocarpine and timolol)

structures of the eye and provide a three-dimensional image. The slit lamp provides valuable information, particularly when examining the cornea and the anterior chamber. The three-dimensional microscopic capability is best demonstrated when examining the intricate topography of the iris.

It may be helpful to set up the slit lamp before the patient is in the room until one feels comfortable using the slit lamp. Place one hand against the middle of the forehead bar in the examination plane to help become familiar with the capabilities of the machine and the joystick. Practice focusing the slit lamp on the details of the skin on your hand. Adjust the focus and depth of vision by sliding the joystick to move the entire slit lamp apparatus forward and backward. Slide the joystick side to side to scan across and examine the entire width of the hand. Rotate the joystick

FIGURE 185-21. An alternative to an eyelid retractor. **A.** Unfold a paper clip and bend it into shape with a hemostat. **B.** Paper clips used to retract the eyelids.

clockwise and counterclockwise to move the line of vision up and down.

Place the slit lamp in the standard position. It takes very few adjustments of the slit lamp to complete the entire examination. The slit lamp can be focused and locked in position with the knob located on the table base for procedures that require the hands to be

FIGURE 185-22. The slit lamp. **A.** Photograph of an example. **B.** The parts of the slit lamp are labeled.

B

FIGURE 185-22. (Continued)

free (e.g., foreign bodies embedded within the cornea). This allows one hand to hold the eyelids open while using the appropriate tool in the other hand.

SETTING UP THE SLIT LAMP

The slit lamp has many parts, most of which are capable of movement. The slit lamp components are often moved into a state of complete disarray by previous users. It is important to start by readjusting the slit lamp to a “standard operating position.”

The body of the slit lamp has three rotating arms. The neutral position is designated as 0° and the center of the chin rest is designated 180°. The lower arm rotates the binocular microscope. It is rarely, if ever, necessary to move the rotating binocular microscope from the 0° position for the purposes of an ED examination. The next two arms are moved as a unit. The lower arm rotates the light 90° in either direction. The light source remains directed toward

the structure that is being focused upon. The angle of the light is changed when the arm is rotated up to 90° in either direction. The standard position for the light is to rotate it 45° to the Emergency Physician's left to examine the patient's right eye and 45° to the Emergency Physician's right to examine the patient's left eye. Rotation of the upper arm independently rotates the slit of light in the coronal plane. It is unnecessary to rotate the two upper arms independently during a routine examination.

The eyepieces of the binocular microscope can be adjusted and focused independently in accordance to the Emergency Physician's needs. The standard starting position is in the 0 and 0 position. The eyepieces can be adjusted to compensate for refractory errors and to correct for the interpupillary distance.

Two levels of magnification are typically available (e.g., 10× and 16×). The switch to change magnification is located just below the eyepieces. The standard beginning position is low magnification. The higher power may be helpful when examining the details of the

FIGURE 185-23. The light of the slit lamp. **A.** A narrow slit to focus on the cornea. **B.** A focused beam of light directed from a 45° angle illuminates the anterior chamber.

cornea or looking for cellular or inflammatory material within the anterior chamber.

The focused light can be adjusted in color, horizontal width, intensity, and vertical width. The standard position is for the light to be at its maximum size with a circular beam of white light at a moderate intensity. This position is used for scanning the eye and examining the external structures. Three independent adjustment mechanisms interact to create the most appropriate illumination to meet examination needs.

The color of the light and the intensity of the light originate from the same mechanism. Most of the positions represent variations in intensity of a white light. There are two options for color. The cobalt blue light is used for emphasizing corneal lesions that pick up fluorescein stain. The green light or red filter is helpful for patients who cannot tolerate the white light secondary to photophobia. This green light will cause red structures to appear darker or black.

The horizontal width of the light can be adjusted with the knob located at the base of the middle arm. The light can be narrowed to 1 or 2 mm or a “slit” for evaluating the depth of corneal lesions (**Figure 185-23A**). The vertical control is used in conjunction with the horizontal control. Narrow the horizontal width to 2 to 3 mm and the vertical width to 2 mm when examining the anterior chamber. This creates a small focused beam. Rotate the light 30° to 60° to illuminate the depth of the anterior chamber (**Figure 185-23B**). This orientation is most beneficial when attempting to identify cellular or inflammatory material within the anterior chamber.

Several portable slit lamps are available (**Figure 185-24**).¹⁸ The Kowa SL-17 (Kowa Company LTD, Torrance, CA) is a hand-held device (**Figure 185-24A**). It uses AAA batteries and can be used for 140 minutes. It is less than 9 inches tall, has two magnifications, three slit widths, and a blue filter. The Arclight (Arclight Medical, Liverpool, United Kingdom) is a pocket ophthalmoscope and otoscope (**Figure 185-24B**). It charges with a USB cable or sunlight. It is meant for use in low-income countries, for mission work, and in areas where it is impractical to carry and use a regular slit lamp.

PATIENT POSITIONING

Cleanse the chin rest and the forehead bar with an alcohol swab before the slit lamp is used to examine a patient. The patient must be able to tolerate a seated position, leaning slightly forward with their head placed in the chin rest and their forehead pressed against the bar to use the slit lamp (**Figure 185-25**). The slit lamp examination cannot be completed in a patient who cannot remain in a seated position. Patients will often need to be reminded to keep their head in the chin rest and their forehead against the bar. Subtle movements from this position will change the viewing plane and disrupt

FIGURE 185-24. Portable slit lamps. **A.** The Kowa SL-17. (Photo courtesy of Kowa Co. Ltd, Torrance, CA.) **B.** The Arclight. (Photo courtesy of Arclight Medical, Liverpool, United Kingdom.)

the focus on the structures of the eye. Always check the patient's position if you are having difficulty focusing the slit lamp.

The slit lamp can be adjusted to match the height of a chair or stretcher. The table moves up and down by adjusting the lever underneath the front of the table. The level of the chin bar can be adjusted to account for the subtle differences in the length of individual patient faces. Rotate the knob located at the base of the chin

FIGURE 185-25. Patient positioning in the slit lamp.

rest apparatus to move it up and down. Raise or lower the chin bar so that the reference mark located below the forehead bar is at the patient's eye level.

Use the joystick to move the slit lamp and scan the patient's eye. The patient must keep their eye in a fixed position while the Emergency Physician uses the joystick to move the slit lamp and scan the eye. Instruct the patient to focus their eye on your shoulder or earlobe.

THE SLIT LAMP EXAMINATION

The slit lamp examination begins with an overall microscope-enhanced evaluation of the external structures of the eye including the lash line, the bulbar conjunctiva, the palpebral conjunctiva, and the lacrimal puncta. The cornea is best evaluated primarily with a wide beam and the fine details are evaluated with the slit. **Do not focus the light into the pupil for an extended time.** It is very uncomfortable for the patient and may result in injury. The normal cornea is perfectly clear and homogeneous. Note any deviation. Specific abnormalities are best documented in writing in addition to a basic schematic diagram.

The anterior chamber should be clear and without particulate matter. It may be difficult initially to identify cells floating in the anterior chamber. They appear like "dust in a sunbeam." The cells, if not clumped, are barely visible with the microscope at the lowest magnification. They often reflect the light slightly and this may not catch the examiner's eye. **Pay special attention to the lower one-fourth of the anterior chamber because cells and inflammatory products tend to settle and may form a meniscus in the upright position.** Flare is the noncellular inflammatory material in the anterior chamber that makes the aqueous humor appear hazy or gelatinous. Flare can obscure the details of the iris. Use the high-power magnification to identify particulate matter after scanning the anterior chamber with the low-power magnification.

ADMINISTRATION OF FLUORESCEIN

Repeat the corneal examination with the aid of fluorescein stain after the slit lamp examination is completed without stain. **Fluorescein is a hydrophilic substance that stains and illuminates any portion of the cornea where there is a breach in the epithelium.** The addition of fluorescein helps to illuminate corneal lesions that might otherwise go unrecognized (e.g., corneal abrasions or keratopathy associated with viral infections). Fluorescein is most

FIGURE 185-26. Instillation of fluorescein stain. **A.** Fluorescein-tipped strips. **B.** Aqueous fluorescein solution.

commonly packaged as individual single-use strips. There is the potential for infectious agents to be transmitted when one fluorescein strip is used for both eyes. Take care to avoid iatrogenically transmitted infections.

Remove contact lenses before the slit lamp examination and fluorescein staining. Place a small drop of saline or topical ophthalmic anesthetic solution onto the tip of the fluorescein strip. Retract the lower eyelid by placing pressure on the skin overlying the inferior orbital rim and distracting it downward (**Figure 185-26**). Ask the patient to look upward to facilitate the administration of the stain and to avoid inadvertent corneal injuries caused by the strip. Touch the fluorescein strip lightly against the palpebral conjunctiva of the inferior eyelid (**Figure 185-26A**). Remove the fluorescein strip. Ask the patient to gently blink and distribute the fluorescein across the entire eye.

Aqueous fluorescein solution can be used as an alternative to the paper strips. Retract the lower eyelid and instill two drops of fluorescein into the cul-de-sac of the lower eyelid (**Figure 185-26B**). The liquid solution or the tip of the applicator can become contaminated and transmit infection.

A small amount of fluorescein is required to adequately stain the cornea. A common mistake is to apply an excessive amount of fluorescein stain. This illuminates the entire tear film and makes it difficult to evaluate subtle lesions on the cornea. Ask the patient to blink several times to remove the excess fluorescein from the cornea. This maneuver will not remove the fluorescein adhering to any corneal defects. Place one or two drops of sterile saline or eyewash onto the eye if blinking does not remove the excess fluorescein. Avoid the use of excessive fluorescein as it is likely to obscure the exam and potentially stain the patient's skin.

The underlying cell layers of the cornea will hold the fluorescein stain if the corneal epithelium is injured. This allows corneal lesions to be visualized. Use the cobalt blue light, preferably in conjunction with the slit lamp, to identify and evaluate any corneal lesions that become apparent. The regions that stain with fluorescein and are visible with the cobalt blue light will appear bright yellow to yellow-green (**Figure 185-27**). **The green light on the ophthalmoscope and the slit lamp are not intended to be used**

to illuminate the fluorescein stain. The green light will enhance the stain in some circumstances but is not as reliable as the cobalt blue light source.

The Seidel test uses fluorescein to assess the presence of anterior chamber leakage of a perforated eye (**Figure 185-28**).¹⁵ It is named after the German Ophthalmologist Erich Seidel. The fluorescein “flows” from the site of an eye perforation with the aqueous humor.

EYEDROP ADMINISTRATION

TRADITIONAL METHODS

Topical ophthalmologic medications are used for examining and treating the eyes. Eyedrops and ophthalmologic ointments are most effectively and accurately instilled within the lower eyelid (**Figure 185-29**). Instruct the patient to direct their head toward

A

B

C

FIGURE 185-28. The Seidel test. **A.** The fluorescein attached to the injury. **B** and **C.** Progression of the aqueous humor flow. (Used with permission from reference 15.)

the examiner with their eyes looking upward (**Figure 185-29A**). Patients often close their eyes at this point. Retract the lower eyelid without placing pressure on the globe and expose the inferior cul-de-sac (**Figure 185-29B**). Apply the drops or ointment in the cul-de-sac (**Figure 185-29C**). **Close the eyelid and apply thumb pressure over the lacrimal duct (Figure 185-29D).** This prevents the liquid medicine from immediately draining through the nasolacrimal duct and into the nose. Instruct the patient to blink once or twice to quickly distribute the medication across the globe. Application of pressure on the lacrimal duct is unnecessary if instilling an ophthalmic ointment.

UNCOOPERATIVE PATIENTS

Some patients require but do not want medication in their eyes (e.g., infants, small children, and those with altered mental status). Prying the eyes of these patients open and applying the drops is difficult for both the Emergency Physician and the patient. Forcefully opening the eyelids is potentially dangerous because secondary injuries may occur. Most medication is typically applied to the Emergency Physician's hand or the stretcher as anyone who has tried this approach knows. An alternative approach in this situation is advisable.

The problem is the uncooperative patient squeezes their eyes closed tightly. Place the patient supine with an assistant holding the head in a fixed upright position with the eyes facing the ceiling to overcome this challenge (**Figure 185-30**). Note the small anatomic depression created over the medial canthus of each eye when they are closed tightly. Place the eyedrops in this anatomic depression to create a shallow pool (**Figure 185-30**). Firmly maintain the patient's head in this position until they spontaneously open their eyes and allow the medication to spread across the globe.

OPHTHALMIC ANESTHETIC AGENTS

Two types of eye medications are required in drop form for most routine ophthalmologic examinations (i.e., a topical ophthalmic anesthetic agent and a dilating agent). **Topical ophthalmic**

FIGURE 185-29. The instillation of eyedrops. **A.** Grasp the lower eyelid. **B.** Pull the lower eyelid downward and outward to expose the cul-de-sac. **C.** Place the drops into the cul-de-sac. **D.** Apply thumb pressure over the lacrimal duct to prevent drainage of the drops into the nose.

anesthetic agents provide relief from eye pain and photophobia.

This may help the patient to cooperate with the necessary examination. Topical ophthalmic anesthetic agents may be used as adjuncts to fluorescein application and to facilitate the placement of eyelid retractors. They may at times be used as an adjunctive diagnostic tool. There are several possible causes of eye pain and photophobia that must be differentiated, some of which may coexist. Complete symptom relief with a topical ophthalmic anesthetic agent suggests that the etiology of the pain is from the conjunctiva or cornea.

FIGURE 185-30. The instillation of eyedrops in an uncooperative patient.

Tetracaine hydrochloride and proparacaine hydrochloride are the most commonly available agents. Their onset of action and duration of action are similar. The onset is within 1 minute and lasts approximately 10 to 20 minutes. Tetracaine hydrochloride (Pontocaine) instillation often results in a transient stinging sensation that lasts 3 to 10 seconds before dissipating. Proparacaine hydrochloride (Ophthetec or Ophthaine) does not result in the stinging sensation.

Topical ophthalmic anesthetic agents are toxic to corneal epithelial cells and can delay corneal healing.^{19,20} They are currently used in the ED only to aid in the diagnosis and evaluation of an eye problem. As a rule, they are not prescribed for treatment outside the ED. These agents are currently being used for up to 4 days on an outpatient basis after photorefractive keratotomy surgery and some other conditions.²¹ Several small studies suggest these agents are safe to use for a few days without adverse effects.²²⁻²⁵ The ED practice of not prescribing topical ophthalmic anesthetic agents for outpatient use may change. A large study is needed to look at the safety of using these medications as an outpatient. The decision is up to the individual Emergency Physician. Do not consider using topical anesthetics for complicated corneal abrasions (e.g., 36 hours or longer after injury, both eyes injured, children, contact lens wearers, contaminated wounds, herpetic keratitis, tetracaine allergies, and unreliable patients). Use dilute 0.5% topical anesthetics if they are prescribed and for no more than 48 hours.

PUPILLARY DILATING AGENTS

Dilating agents are used as an adjunct to the funduscopic examination. **Always perform and document a complete pupillary examination before instilling dilating agents.** It is important to document the use of dilating agents and the time of administration.

Avoid using dilating agents in patients who require serial pupillary examinations to follow their neurologic status. Dilating agents are contraindicated in patients with a known or suspected narrow iridocorneal angle. Dilating the pupil may result in acute angle-closure glaucoma. Some intraocular lens implants may become dislodged if the pupils are pharmacologically dilated. Inquire and document any glaucoma, known narrow angles, and eye surgery prior to dilating any pupils. Consult an Ophthalmologist before dilating these patients' eyes.

Dilating agents are categorized as mydriatics and cycloplegics. All dilating agents are covered with a red cap. Mydriatic agents directly dilate the pupil whereas cycloplegics paralyze the ciliary muscles. Do not use cycloplegic agents for patients who require serial neurologic examinations. Choose a noncycloplegic mydriatic agent (e.g., phenylephrine) to dilate the pupils of a patient requiring serial examinations. The duration of action is significantly shorter than that of a cycloplegic agent. Phenylephrine is systemically absorbed and may be inappropriate for patients with hypertension or cardiac conditions. A combination of a mydriatic agent (e.g., phenylephrine) and a shorter-acting cycloplegic agent (e.g., cyclopentolate) is optimal when maximal dilation is necessary or when a single agent is ineffective.

Most EDs stock or have access to five dilating agents. The choice of agents depends upon the length of time required for dilation, the need for a cycloplegic agent, and the need for a mydriatic agent. Atropine (Isopto Atropine) produces cycloplegia lasting 5 to 10 days and mydriasis lasting 7 to 14 days. Cyclopentolate (Cyclogyl, AK-Pentolate, Pentolair) produces cycloplegia lasting 6 to 24 hours and mydriasis lasting 24 hours. Homatropine (Isopto Homatropine) produces cycloplegia and mydriasis lasting 1 to 3 days. Phenylephrine (Neo-Synephrine, Mydrin, Relief) produces mydriasis lasting 5 hours. Tropicamide (Mydriacyl) produces mydriasis lasting 4 to 6 hours.

THE FUNDOSCOPIC EXAMINATION

A fundoscopic examination is an essential part of every eye evaluation. Examine the fundus with an ophthalmoscope (Figure 185-31). It is particularly helpful when the patient complains of visual disturbances or visual loss. Examine the patient's right eye first. Hold the ophthalmoscope in the right hand and use the right eye to examine the patient's right eye. Remember "right eye to right eye and left eye to left eye" or the Emergency Physician may otherwise find they are in an awkward nose-to-nose position with the patient. Instruct the patient to focus the eye not being examined on a fixed object over the Emergency Physician's shoulder and approximately 6 to 8 feet away. It is important that the patient maintain their focus on the object throughout the complete examination of the eye. It is helpful to tell them to focus on the object with the eye not being examined. This will result in a stationary eye for examination.

Set the ophthalmoscope initially at 0. Adjust the dial as the examination begins to adjust for refractory errors. Moving the dial into the red numbers moves the point of focus forward toward the red retina. Moving the dial into the black numbers moves the point of focus closer to the Emergency Physician. Approach the eye from a slightly lateral position to quickly identify the medial position of the optic disk. Position the ophthalmoscope as close as possible to the patient's eye without making contact. Imagine looking at the fundus through a peephole. The closer you get, the wider the view on the other side. By the same analogy, the larger the peephole, the better the view on the other side. Dilate the patient's pupils if safe to do so to obtain the best results from the ophthalmoscope examination.

A

B

FIGURE 185-31. The ophthalmoscope. **A.** A standard version. **B.** The Panoptic.

Adjust the diameter of the light down to the size of the patient's pupil to avoid the bright reflection from the iris if dilation is not possible. This bright reflection is a common reason for inadequate visualization of the fundus. The patient's eyes are often moving if the structures seem to move in and out of focus. Remind the patient to focus on one point. Inspect the eye grounds for uniformity (Figure 185-32). The normal color of the fundus is creamy peach to pink but may be pigmented in darker skinned people. A pale fundus with a small cherry-red spot in the region of the macula suggests an infarction generally associated with a retinal artery occlusion. The optic disk is located on the nasal aspect of the fundus. If the

FIGURE 185-32. The normal fundus as seen through an ophthalmoscope. The macula and optic disk are clearly visible.

optic disk does not come into view, follow the blood vessels that extend from the disk to the periphery of the retina. The disk margin should be sharp except the nasal aspect that may appear slightly blurred in a normal eye (**Figure 185-32**). Papilledema appears as diffusely blurred disk margins (**Figure 185-33**). Papilledema may be the result of localized inflammation of the optic nerve or elevated intracranial pressure (**Figure 185-33**).

The veins will appear darker and wider than the arteries (**Figure 185-32**). Evaluate the blood vessels for evidence of hemorrhages and irregularities. Acute hemorrhages may be helpful in the diagnosis of a variety of problems (e.g., hypertensive emergency or

FIGURE 185-33. Papilledema as seen through the ophthalmoscope.

the shaken baby syndrome). Carefully consider the clinical setting. A helpful finding in the patient suspected of having increased intracranial pressure is the presence or absence of venous pulsations. Venous pulsations are best seen as the veins cross into the optic cup. The presence of venous pulsations is a normal finding. The first sign as the intracranial pressure rises is a loss of venous pulsations followed later by papilledema. The green light or red filter helps to provide a sharper image when evaluating the retinal vessels in detail.

Examine the fovea and the surrounding macula (**Figure 185-32**). This area is located approximately 2 to 3 disk diameters (DD) lateral to the optic disk. Instruct the patient to look directly into the light to bring the fovea and macula into view. The target setting on the ophthalmoscope is helpful for this purpose. Look using the ophthalmoscope turned to the target. Instruct the patient to look directly into the center of the target. The fovea will be found at the center of the target in your view.

Examine the vitreous chamber for evidence of a vitreous hemorrhage when a retinal detachment is suspected or when the patient complains of floaters. The fluid within the vitreous chamber is gelatinous so blood within it does not dissipate quickly. Blood within this chamber appears as clouds, spots, or veils to the patient and the Emergency Physician. Their color is typically described as black or red. Set the ophthalmoscope to +10 to move the point of focus anteriorly toward the Emergency Physician to evaluate the vitreous. Dial the ophthalmoscope down as the examination proceeds. Each click results in focusing a little deeper within the vitreous chamber until the point of focus is upon the retina at the posterior aspect of the chamber.

INTRAOCULAR PRESSURE MEASUREMENT

Include the measurement of intraocular pressure in the eye examination (Chapter 188). It is particularly important in patients with eye pain and visual loss.

OCULAR ULTRASOUND

The application of bedside ultrasound (US) has become a widely used tool for the rapid diagnosis of ocular pathology in the ED. Its use by Ophthalmologists has been described as early as the 1950s. The use of US has been popularized by high-resolution machines allowing Emergency Physicians to detect subtle abnormalities (e.g., globe rupture, increased intraocular pressure, lens dislocation, retinal detachment, retinal hemorrhage, and vitreous hemorrhages). This section covers the basic anatomy, common ocular pathology, and techniques of ocular US.²⁶⁻²⁸ An US examination can be performed quickly and without the patient leaving the ED; in addition, US machines are readily available and use no ionizing radiation.

ULTRASOUND TECHNIQUE

Perform ocular bedside US with a high-frequency, 7.5 to 10 MHz, linear transducer to scan the eye in two axes. Place the patient supine or in a 45° sitting position with their neck slightly extended. Apply a generous amount of US gel over the closed eye (**Figure 184-34A**). An alternative to having the patient keep their eyelid closed is to place a clear dressing (e.g., Tegaderm) over the closed eyelid (**Figure 185-34B**) and to place the gel over it. Brace the hand on the forehead to balance the transducer to offset any pressure over the eye. It is extremely important to avoid pressure, especially in the case of an undiagnosed globe rupture, in which US is contraindicated. Orient the transducer marker toward the patient's head in a longitudinal axis or to the right of the patient in a transverse axis while the patient is asked to look to the right and left to create a three-dimensional view of the eye (**Figure 185-35**).

FIGURE 185-34. US of the eye through the closed eyelids. **A.** Without a clear dressing. (Used with permission from reference 33.) **B.** With a clear dressing. (Used with permission from www.aliem.com.)

OCULAR ULTRASOUND ANATOMY

A detailed overview of the eye anatomy is beyond the scope of this chapter. This section covers the relevant structures of the eye that can be visualized using US. The anatomy of the eye and surrounding structures can be seen in **Figures 185-1, 185-35, and 185-36.**

RETINAL DETACHMENT

Retinal detachments can be difficult to diagnose in the ED. The visualization of the posterior structures of the eye using US can make the diagnosis less challenging and may facilitate rapid treatment in the case of time-sensitive pathology (**Figure 185-37**).^{26,29} Detection of retinal detachment has a sensitivity of up to 97% and specificity of 92%. Other small studies have shown a sensitivity of up to 100% and specificity of 83%. US findings of retinal detachments are significant for a string-like echogenic structure attached to the posterior globe.^{26,29}

VITREOUS HEMORRHAGE

The diagnosis of a vitreous hemorrhage suspected by history and ophthalmic examination may be confirmed with US.^{26,30} Hyperechoic globular and/or granular opacities will be present in the posterior globe (**Figure 185-38**). The appearance will be delineated

FIGURE 185-37. Retinal detachment. An artist illustration (left) and an US (right). The retina is completely detached in the US image. The retina is firmly attached to the optic nerve posteriorly and the ora serrata anteriorly to produce the V shape. (Used with permission from reference 35.)

FIGURE 185-38. Vitreous hemorrhage. An artist illustration (left) and an US (right). (Used with permission from reference 35.)

FIGURE 185-39. Optic nerve sheath diameter (ONSD) measurement to assess for increased intracranial pressure. Distance 1 is the distance (i.e., 3 mm) behind the optic disk where the ONSD is measured. Distance 2 between the white arrows is the ONSD. (Used with permission from reference 35.)

when asking the patient to look to their left and right. These ocular movements create a swirling appearance in the posterior globe. This is a classic finding in vitreous hemorrhages known as the “washing machine” sign. Increasing the gain on the US machine may be necessary to better visualize posterior structures, especially with subtle abnormalities.^{26,30}

INCREASED INTRACRANIAL PRESSURE

Intracranial pressure can be assessed with accuracy with the use of ocular US by measuring the optic nerve sheath diameter.³¹⁻³³ Several studies have compared its use with computed tomography for assessment of intracranial pressure. A meta-analysis shows a sensitivity of 95% and specificity of 95%. The optic nerve sheath appears as a hyperechoic vertical structure in the posterior globe (**Figure 185-39**). Measure the optic sheath diameter 3 mm posterior to the globe (**Figure 185-39**). An optic nerve sheath diameter more than 5 mm corresponds to an intracranial pressure above 20 mmHg. Measure the optic nerve sheath diameter bilaterally for comparison.^{28,33,34}

SUMMARY

Approach all eye complaints with a detailed history that includes a chief complaint, the duration of symptoms, and the natural history of their evolution. It is important to inquire about exposures and trauma. The past medical history must include the patient's baseline visual acuity and any history of eye problems. Perform a complete examination on all patients with eye complaints. Always document an accurate visual acuity and carefully inspect the eye structures. A thorough approach in all patients with eye complaints improves diagnostic accuracy. The result is a decrease in morbidity and long-term complications in this vital sensory apparatus.

Contact Lens Removal

Scott A. Heinrich and Dino P. Rumoro

INTRODUCTION

The Emergency Physician must be familiar with the proper technique of removing soft and hard contact lenses from patients who are unable to do so on their own. Patients with altered mental status are at risk of corneal damage if contact lenses remain in place. Healthy individuals who wear contact lenses overnight experience a 4- to 15-fold increase in the risk of corneal injury compared with those who remove their contact lenses daily.¹ The explanation for this increased risk of injury is based on the development of corneal hypoxia and an immune response to antigens present on the lens surface, both of which lead to an inflammatory response and susceptibility to infectious organisms.¹ This results in an increased incidence of ulcerative keratitis, *Pseudomonas aeruginosa* infection, and corneal neovascularization.^{2,3}

ANATOMY AND PATHOPHYSIOLOGY

Contact lenses rest on a three-layer tear film (i.e., outer lipid, middle aqueous, and inner mucus layer) that covers the corneal and conjunctival epithelium. This tear layer provides oxygen and nutrients to the avascular cornea. The cornea receives nutrition from blood vessels at the limbus and the aqueous humor. It is believed that contact lenses increase tear evaporation and disrupt the three-layer tear film.⁴ This leads to the lack of corneal oxygenation and the symptoms of dry eye.⁴ A dry eye causes discomfort and corneal edema with resultant hazy vision. The normal blinking action initiates contact lens movement and a “fresh” flow of oxygenated tears over the cornea in an awake patient. Blinking is not present in the sleeping or comatose patient.

The normal resting position of the contact lens is over the cornea. It may occasionally drift from the center of the eye and relocate. It may relocate over the sclera, in various parts of the eye socket, or under the upper eyelid. **Thorough exploration of all aspects is essential when evaluating an individual for the presence of contact lenses prior to their removal.** Inspect under the lower eyelid margin and eversion of the upper eyelid. This requires double eversion of the eyelid for identification and retrieval (Chapter 185).⁵ **Failure to adequately perform this examination can lead to the mistaken belief that a contact lens does not exist.** A contact lens that remains in place acts as a foreign body and can lead to chronic irritation, inflammation, and development of a mass. Mass development from a retained contact lens typically occurs in the upper fornix of the eyelid.⁵

INDICATIONS

Contact lenses must be removed from any patient who is unconscious or suffers an ocular injury. Remove contact lenses before fluorescein stain is used to examine the eye. Fluorescein can permanently stain the contact lens material. Give patients the opportunity to remove their own contact lenses if there are no contraindications (i.e., immobilization or ocular trauma). Patients are usually quite adept at removing their own contact lenses. Remove the contact lenses if the patient is unable to remove them or cannot remove them.

CONTRAINDICATIONS

The only absolute contraindication to removing a contact lens would be in the case of a ruptured globe. Leave the contact lens in place for the Ophthalmologist to remove at the time of their examination and/or surgical repair. Extreme caution must be exercised to avoid unnecessary pressure on the eye to not complicate the injury when severe ocular damage has occurred. Place an eye shield and not an eye patch to avoid pressure on the globe with resultant exacerbation of the injury (Chapter 193).

EQUIPMENT

- Normal saline
- Two cups, labeled “left” and “right”
- Hard lens remover suction cup device, optional
- Soft lens remover device, optional
- Cotton-tipped applicators

PATIENT PREPARATION

Explain to the patient, if they are awake, that their contact lenses must be removed. Explain the risks, benefits, and alternative procedures to the patient and/or their representative. A signed consent is not required to remove a contact lens. Place the patient sitting or supine, whichever is most appropriate for the current clinical situation. Place several drops of a saline solution onto the eye and wait 5 to 10 minutes to allow the saline to penetrate the lenses. This maximally moistens the contact lenses to the point where they can be seen to slide easily over the surface of the eye when the patient blinks.

All contact lenses should be centered over the cornea for ease of removal by gentle manipulation of the eyelids. The lenses may become displaced from the cornea. Care must be taken to search for the lens in other parts of the eye socket. Shine a penlight at an angle to the eye to aid in the search. A common location for a displaced contact lens to migrate is under the upper eyelid. **Evert the upper eyelid (Chapter 185) if a contact lens cannot be found elsewhere to complete the search before concluding that the lens fell out or the patient is not wearing contact lenses.** Instill fluorescein into the eye if the patient still insists that it is present. **The fluorescein will pool around the edges of the contact lens and make it easy to locate.** Warn the patient that fluorescein may permanently stain their contact lens.

Prepare the equipment. Locate the equipment required to remove the contact lenses. Label two cups with “left” and “right” in which to place the contact lenses after they are removed. Fill the cups with enough saline to cover the contact lenses. Wear powderless gloves to prevent the powder from irritating the eye. Wipe powdered gloves clean with a saline- or a water-moistened towel to remove the powder. Powdered gloves can be placed under running water to flush away the powder.

FIGURE 186-1. Examples of contact lenses. From left to right: soft lens, hard lens, and scleral lens.

HARD CONTACT LENS REMOVAL TECHNIQUES

A hard contact lens can be identified by its small size of 6 to 10 mm (**Figure 186-1**). It is smaller than the cornea. Center the hard contact lens on the cornea. Place the index finger (or thumb) of one hand at the base of the eyelashes of the upper eyelid and the index finger (or thumb) of the opposite hand at the base of the eyelashes of the lower eyelid (**Figure 186-2A**). Gently, but firmly, approximate the eyelids by moving them toward the center of the cornea until the margins of the eyelids touch the edges of the hard contact lens (**Figure 186-2B**). Press slightly harder on the lower eyelid until the bottom edge of the hard contact lens lifts off the cornea using the edge of the lower eyelid as a fulcrum (**Figures 186-2C and 186-2D**). Continue to push the eyelids together until the hard contact lens is lifted completely off the cornea and can be easily grasped.^{6,7}

The patient who is awake and alert may not like the Emergency Physician's fingers near their eyes. Pull the skin of the lateral margin of the eyelids laterally with an index finger (**Figure 186-3A**). Alternatively, place one finger on the lateral edge of the upper eyelid and one finger on the lateral edge of the lower eyelid and pull laterally (**Figure 186-3B**). Instruct the patient to look downward and inward toward their nose. The hard contact lens will pop off the cornea. Grasp and remove the contact lens. This technique does not put as

FIGURE 186-3. Alternative hard contact lens removal techniques. These methods do not apply pressure onto the globe. Apply laterally directed pressure to the skin lateral to the eyelids (**A**) or to the eyelids (**B**) to "catch" the contact lens and pop it off the eye.

much pressure on the globe as the previous technique which is an advantage if the patient has ocular trauma.

A commercially produced suction cup-like rubber device, resembling a golf tee, can be used to remove hard contact lenses if available (**Figure 186-4**). Moisten the surface of the device with a drop of saline. Gently touch the suction cup to the center of the hard contact lens. Suction will form and result in the hard contact lens adhering to the device. Lift the device and the attached contact lens from the cornea. **Slide the hard contact lens sideways to remove it from the suction cup. Do not attempt to pull the hard contact lens off the suction cup as this may damage the contact lens.**

A final technique involves the use of a cotton-tipped applicator (**Figure 186-5**). Moisten the cotton with saline. Place the cotton-tipped applicator over the lower edge of the hard contact lens (**Figure 186-5A**). Carefully and gently slide the hard contact lens off the cornea and onto the sclera with the moistened cotton-tipped applicator. Gently press the cotton-tipped applicator into the sclera and under the edge of the hard contact lens (**Figure 186-5B**). Lift

FIGURE 186-2. Hard contact lens removal. **A.** Use both thumbs to open the eyelids. **B.** Close the eyelids until the edges of the eyelids just contact the lens. **C.** Push the edge of the lower eyelid under the edge of the contact lens to pop it off the eye. **D.** Lateral view of the lower eyelid pushing the contact lens off the eye.

FIGURE 186-4. Suction cup removal of hard contact lenses. **A.** Suction cup on a plastic handle. **B.** Fingertip-held suction cup.

the hard contact lens from the sclera. **Do not use the cotton-tipped applicator to elevate the hard contact lens from the cornea as this can result in a corneal abrasion.**⁸

SOFT CONTACT LENS REMOVAL TECHNIQUES

Soft contact lenses can be identified by their larger sizes of > 12 mm (**Figure 186-1**). They usually extend to, or just beyond, the corneal-scleral junction. There are numerous techniques to remove a soft contact lens (**Figures 186-6, 186-7, and 186-8**). The easiest and

FIGURE 186-5. A cotton-tipped applicator to remove a hard contact lens. **A.** Place a moistened cotton-tipped applicator against the lower edge of the hard contact lens. Push the hard contact lens onto the sclera. **B.** Push the moistened cotton-tipped applicator under the edge of the contact lens to lift it off the eye.

simplest method is to remove it manually (**Figure 186-6**). Retract the lower eyelid with the nondominant index finger (**Figure 186-6A**). The soft contact lens will slide partially onto the conjunctival surface of the lower sclera. Gently grasp the soft contact lens between the thumb and index finger of the dominant hand. Pinch the fingers together and remove the soft contact lens.

A second technique to remove soft contact lenses is illustrated in **Figure 186-6B**. Gently place the index finger and thumb of the nondominant hand on the upper and lower eyelids, respectively. Retract the eyelids. Gently grasp the soft contact lens between the thumb and index finger of the dominant hand. Slide the soft contact lens inferiorly. Gently pinch the fingers together to pull the soft contact lens from the eye.⁶

FIGURE 186-6. Manual soft contact lens removal techniques. **A.** Pull the lower eyelid downward and grasp the contact lens. **B.** Retract the eyelids. Slide the soft contact lens off the cornea and onto the sclera. Grasp and remove the contact lens. **C.** Use the patient's eyelids to pop the contact lens off the eye.

FIGURE 186-7. A tweezer-like device to grasp and remove the soft contact lens.

A third technique to manually remove a contact lens uses the patient's eyelids (**Figure 186-6C**). Place the thumb of the non-dominant hand and dominant hand on the upper and lower eyelid, respectively. Retract the eyelids until the edges of the contact lens are fully visible. Close both eyelids against the superior and inferior edges of the soft contact lens. Continue to close the eyelids until the contact lens pops off the eye. Grasp and remove the soft contact lens with the dominant hand.

A commercially available rubber tweezer-like device can be used to remove soft contact lenses. Place the rubber tips of the device onto the center of the soft contact lenses (**Figure 186-7**). Gently squeeze the tweezers closed using minimal pressure. The soft contact lens will fold and lift off the eye. Remove the soft contact lens from the eye.

A commercially available rubber disc on a stick can be used to remove soft contact lenses. Place the rubber disc over the center of the soft contact lens (**Figure 186-8**). Apply gentle pressure to slide the soft contact lens onto the sclera. Lift the stick to remove the

FIGURE 186-8. A rubber pad to remove a soft contact lens.

attached soft contact lens. The rubber disc may occasionally not stick to the soft contact lens. Apply a drop of saline to the rubber disc and repeat the procedure. The drop of liquid will form a seal between the rubber disc and the soft contact lens.

SCLERAL LENS REMOVAL TECHNIQUES

The scleral lens is essentially a very large, soft contact lens (**Figure 186-1**). It is approximately the size of a quarter and covers the cornea and sclera. Remove the scleral lens using the same techniques described to remove a soft contact lens.

ALTERNATIVE TECHNIQUE

An alternative technique was described to use moistened cotton-tipped applicators (**Figure 186-9**).⁹ This technique uses two moistened cotton-tipped applicators like chopsticks to remove a contact lens. This technique may be used when the patient does not like the Emergency Physician's fingers near their eyes or as an alternative to using one applicator.

AFTERCARE

Place removed contact lenses in the appropriately marked container. Ensure that the contact lenses are covered completely with saline solution. Perform an eye examination using fluorescein eye drops

A

B

FIGURE 186-9. The chopsticks technique. **A.** Frontal view of an adult patient. **B.** Side view of a pediatric patient. (Used with permission from reference 9.)

if the patient complains of eye pain after contact lens removal. The procedure may have resulted in a corneal abrasion.

COMPLICATIONS

Any attempt to remove contact lenses with fingernails or other solid objects not approved for the removal of contact lenses can cause corneal abrasions. Their use must be avoided. Proper contact lens removal techniques can result in corneal abrasions. Do not patch corneal abrasions resulting from contact lens removal to prevent an infectious process.⁸ The suction cup of the hard contact lens remover may occasionally be inadvertently placed on the cornea. **Do not pull it off the cornea.** Slide it to the lateral corner of the sclera and remove it with a twisting motion.

Never remove a contact lens if there is concern for a potential globe perforation. The techniques described in this chapter are gentle yet put pressure on the globe while removing a contact lens. This pressure on the globe may result in extrusion of the intraocular contents (i.e., lens or vitreous) and cause permanent blindness. Use a suction cup device on a hard contact lens or a rubber disc on a soft contact lens if the contact lens must be removed before the Ophthalmologist arrives.

Additional complications include the inability to remove the lens and damage to the contact lens itself.⁸ Consult an Ophthalmologist or Optometrist if a contact lens cannot be removed from the cornea. Desiccated lenses that are not properly rehydrated prior to removal can result in the removal of the corneal epithelium and a corneal abrasion.⁸ A properly hydrated lens will slide easily over the surface of the eye. Apply saline drops onto the eye to hydrate the contact lens prior to removal.

SUMMARY

Removal of contact lenses is a procedure that all Emergency Physicians must be able to perform on any patient who is unconscious, has ocular trauma, or cannot remove their own lenses. Failure to perform this simple procedure appropriately can result in serious ocular damage. The removal of a contact lens is easy, quick, simple, and straightforward. Never remove a contact lens if a globe perforation is suspected unless necessary.

Ocular Burn Management and Eye Irrigation

Steven J. Socransky

INTRODUCTION

Ocular burns are true emergencies and represent a up to 10% of ocular trauma cases.^{1,2} Chemical burns account for the large majority of ocular burns with thermal burns being the second most common cause.³ Most victims are young males.^{2,4,5} The industrial workplace is the most common setting, although a significant number of cases occur in the home.⁴ Assaults are a significant cause of ocular burns in the lower socioeconomic groups of large cities.^{4,6}

Caustic agents are primarily responsible for the most severe chemical ocular burns. Most reports indicate that alkali burns are more frequent than acid burns.^{1,3,4,7} Examples of more common alkalis and acids are listed in **Table 187-1**.^{4,8-15} Ammonia causes the most serious alkali burns.⁴ Calcium hydroxide (i.e., lime) is the most common cause of alkali burns.⁴ Hydrofluoric acid causes the most serious acid burns.⁴ Sulfuric acid is the most common cause of acid burns.⁴ Caustic agents account for only a minority of chemical ocular exposures.¹ Most chemical ocular exposures are due to relatively innocuous noncaustic substances (e.g., shampoos, hair sprays, and personal defense sprays) and therefore do not cause significant or lasting damage.^{1,16-21}

Ocular irrigation is a simple procedure that is commonly employed in the Emergency Department.²² It is potentially an eye-saving procedure in the setting of significant chemical ocular burns. Physicians, nurses, and emergency medical personnel who deal with ocular emergencies should be trained in ocular irrigation. First aid personnel in the workplace should be familiar with the use of ocular irrigation.²³ **Ocular irrigation must be employed rapidly.**^{1,22,24,25} **Delays in irrigation can limit its effectiveness and increase morbidity.**³ A treatment algorithm is shown in **Figure 187-1**.

ANATOMY AND PATHOPHYSIOLOGY

The anterior surface of the globe is the major target of toxins in ocular burns (**Figure 187-2**). The eyelids are the most important protective structure for the eye. The orbicularis oculi muscle is innervated by branches of the facial nerve and closes the eyelids in response to noxious stimuli. The cornea provides little in the way of protection from chemical agents. The cornea is composed of five convex and transparent tissue layers. The cornea's major function

TABLE 187-1 Common Caustic Agents and Their Sources

Substance	Class	pH	Source
Ammonium hydroxide	Alkali	11.6	Fertilizers, refrigerants, sparklers
Calcium hydroxide	Alkali	12.4	Mortar, plaster, cement
Magnesium hydroxide	Alkali	10.0	Sparklers, fireworks
Potassium hydroxide	Alkali	11.0	Oven and drain cleaners
Sodium hydroxide	Alkali	14.0	Lye soaps, airbags, EMLA cream, hair straightener
Sodium hypochlorite	Alkali	11.0	Bleaches, drain cleaners

Sulfurous acid	Acid	1.5	Bleach, refrigerants

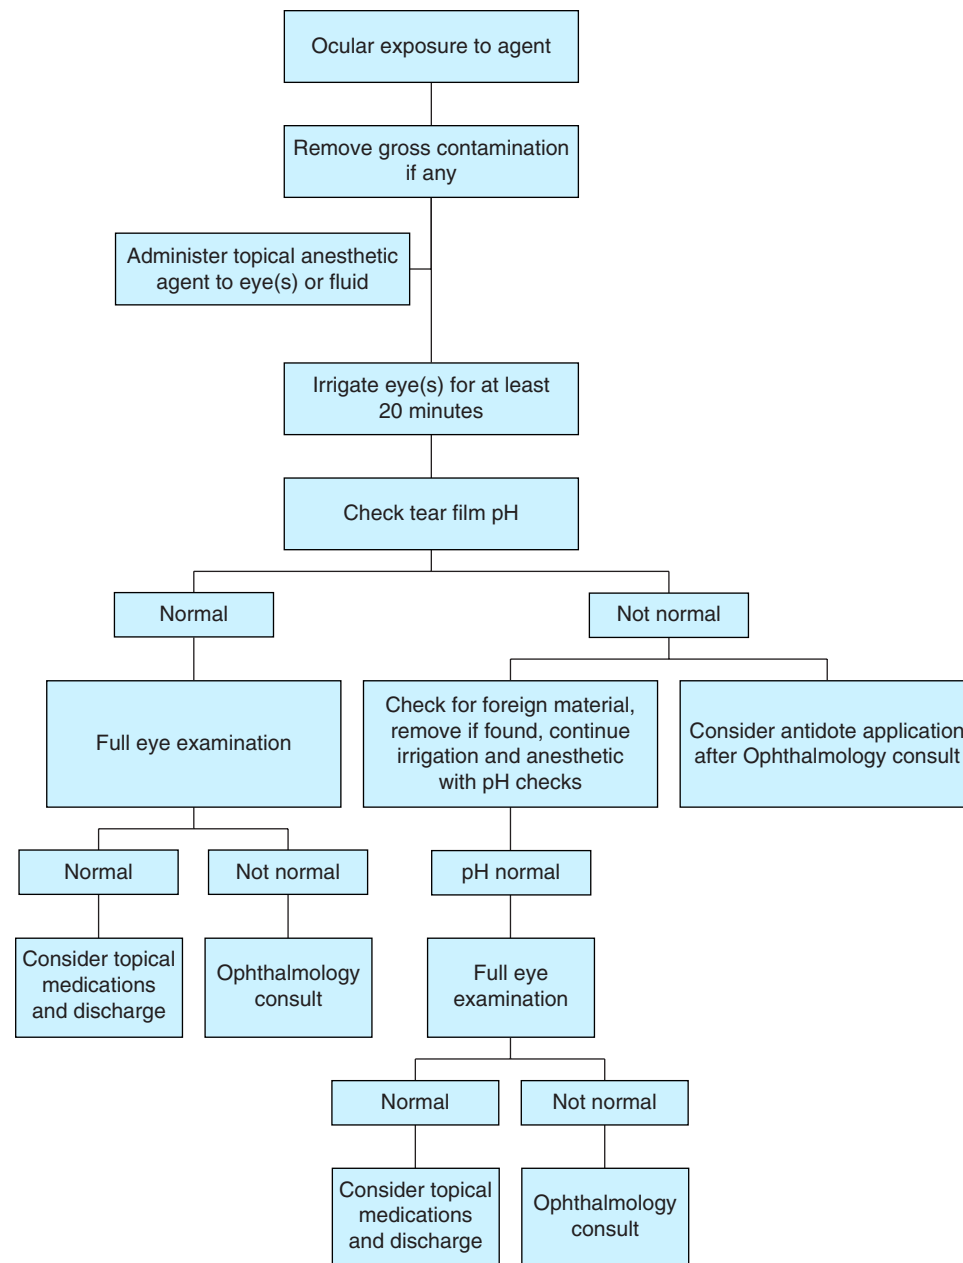

FIGURE 187-1. An algorithm for the Emergency Department management of ocular exposures.

is the refraction and transmittance of light. **The cornea is avascular and exquisitely sensitive to pain.** Extensive burns may be less painful due to destruction of corneal nerve endings and resultant anesthesia.²⁶ The cornea merges with the sclera to form the limbus at its outer margins. Stem cells at the level of the limbus are responsible for regeneration of the corneal epithelium. The corneal epithelium is unable to regenerate when the limbus is damaged. The fibrous sclera is tougher than the cornea and susceptible to chemical injury.

The sclera is covered by the bulbar conjunctiva which becomes the palpebral conjunctiva as it reflects onto the inner surface of the eyelids. These areas of reflection are referred to as the superior and inferior fornices of the upper and lower eyelids, respectively. The spaces between the eyelids and the globe are referred to as the superior and inferior conjunctival sacs (i.e., palpebral sulci). Posterior to the cornea lies the anterior chamber. It contains the aqueous humor. The anterior and posterior chambers are separated by the iris, ciliary body, trabecular meshwork, and lens.²⁷

The damage produced to the eye by toxins depends on several factors: duration of contact; anion or cation concentration; and amount, pH, and inherent toxicity of the chemical.^{24,28} **Alkalis generally produce the most damage.** Alkalis release hydroxyl ions that combine with tissue fatty acids and proteins causing liquefaction necrosis.¹³ The resultant degradation of corneal tissue allows for easy passage of the chemical into the anterior chamber. This causes a rapid rise (e.g., within a few seconds to a few minutes of contact) in aqueous humor pH and consequent damage to the iris, lens, ciliary body, and other ocular structures.^{4,26,29} Damage to these structures and the cornea results in decreased visual acuity, secondary glaucoma, and cataracts. This damage can continue as the anterior chamber pH may remain elevated for hours. **Measurement of tear film pH immediately after irrigation will often yield a normal pH.^{9,10} This may be falsely reassuring.** It may either reflect the pH of the irrigant or a transient neutralization of the tear film pH.²⁶ Alkalis may diffuse from the anterior chamber to the anterior ocular surface several minutes

FIGURE 187-2. Cross-sectional anatomy of the eye and surrounding structures.

after irrigation has been discontinued. This causes the tear film pH to rise again.

Acids cause less damage than alkalis. Acids lead to coagulation necrosis and protein precipitation which usually prevents penetration beyond the cornea.¹³ Exceptions include acids in higher concentration (e.g., sulfuric acid) and hydrofluoric acid which behave more like an alkali.^{4,6,26} These acids can cause damage to deeper structures. Ocular burns caused by weaker acids can progress if treatment is delayed.²⁶

Most noncaustic chemical eye exposures involve nontoxic agents that do not penetrate the cornea and cause only mild and self-limited irritation. Notable exceptions include surfactants and high-concentration lacrimators, both of which can cause damage to deeper structures.^{12,26} Lacrimators in low concentration (e.g., tear gas) stimulate corneal nerve endings and cause pain and tearing. They do not cause deeper injury.²⁶ Surfactants can cause significant damage that is often minimally symptomatic.¹² Most solvents can cause sizable superficial corneal defects. Reepithelialization is the rule and deeper tissues are spared.^{12,26} Corneal injuries due to capsicum (i.e., pepper spray) usually are self-limited injuries with occasional significant corneal defects requiring Ophthalmology follow-up.³⁰

INDICATIONS

The treatment of chemical exposures to the eye is the primary indication for ocular irrigation (**Figure 187-1**). Irrigation should return the patient's vision to the preexposure level in most cases.^{18,19,31} In this setting, irrigation has three principal objectives: immediate dilution of the offending agent, removal of the agent, and normalization of anterior chamber pH.²⁶ Nonembedded foreign bodies that are too small or too numerous to be removed adequately with forceps or a cotton-tipped applicator can usually be removed with irrigation. Foreign bodies that are suspected but cannot be visualized may be removed with irrigation. Certain ocular infections are

treated with antibiotics delivered by eye irrigation, although this is not a usual indication in the Emergency Department.

CONTRAINDICATIONS

There are no true contraindications to ocular irrigation. An **irrigating lens (e.g., Morgan Lens)** should not be used if a deep corneal injury or a foreign body is suspected.³² This lens may cause the foreign body to further injure the cornea or penetrate the globe. It is preferable to carefully employ the traditional method of irrigation using intravenous tubing and eyelid retraction rather than commercial devices that contact the globe in the setting of an actual or potential globe penetration or rupture.

EQUIPMENT

- Topical ophthalmic anesthetic agent, 0.5% proparacaine or 0.5% tetracaine
- Towels and a basin to collect fluid runoff
- Bags of crystalloid solution
- Intravenous tubing
- Gauze pads
- Cotton-tipped applicators
- Lid retractors, paper clip or Desmarres retractor
- Commercial irrigation device (e.g., a Morgan Lens)
- Protective eyewear, gloves, and gowns for healthcare personnel

PATIENT PREPARATION

Patients with ocular chemical burns may also have upper respiratory tract injuries, gastrointestinal tract injuries, and facial burns.¹ Non-chemical traumatic injuries are also possible. Airway, breathing, and circulatory problems should take priority. Significant ocular burns will need to be dealt with early and simultaneously with other problems. Irrigation of the periocular skin should be performed initially with ocular irrigation itself so that residual toxin does not enter the eye and cause further chemical injury.

Patients with isolated ocular injuries often have severe pain that requires parenteral narcotics. If this is the case, a monitored setting is appropriate. Intravenous sedatives and analgesics may facilitate ocular irrigation in a patient with severe pain and blepharospasm. Place the patient supine. Place towels and a basin under the patient's head to collect the runoff irrigant solution. Due to the speed with which ocular irrigation must be started, an explanation of the risks and benefits of the irrigation procedure should be offered to the patient while preparing for and initiating irrigation. Healthcare personnel and first-aid workers in the workplace are at risk for injury themselves. Protective equipment is essential and should be easily and rapidly accessible. Contaminated clothes should be removed and bagged in plastic until they can be cleaned or discarded.¹⁷

TECHNIQUES

A topical ophthalmic anesthetic agent, if immediately available, should first be instilled into the inferior conjunctival sac. Commonly available topical anesthetics include tetracaine and proparacaine. Proparacaine causes less irritation than tetracaine.³³ Each has a duration of action of approximately 10 minutes. Frequent readministration of the topical anesthetic may be necessary every 5 to 10 minutes to ease patient discomfort and facilitate irrigation. An alternative to readministration of local anesthetic would be to add 10 mL of 1% lidocaine to 1 L of crystalloid solution. The addition of lidocaine to the crystalloid solution was compared to an initial

instillation of two drops of tetracaine.³⁴ Lidocaine added to the irrigant decreased the discomfort of irrigation when the irrigation lasted more than 10 minutes.³⁴

OCULAR IRRIGATION

Hang the bag of crystalloid solution at a height of 70 to 200 cm above the patient's head in order to obtain an adequate flow rate.^{35,36} The traditional eye irrigation technique involves directing the flow of crystalloid solution over the globe at a wide-open rate (**Figure 187-3**). Hold the end of the intravenous tubing 3 to 5 cm above the patient's eye to avoid blunt injury to the ocular surface. An assistant is usually needed to hold the eyelids open. Dry gauze pads will facilitate one's ability to maintain a grip on the slippery eyelids and keep them open. Direct the flow of crystalloid solution at the entire surface of the globe including into the conjunctival sacs and down to the conjunctival fornices.^{26,37} Having the patient look in a direction opposite to where the irrigant is directed helps in this regard.³⁸ **Although one can point the stream of irrigant directly at the conjunctiva, it is better to direct it across the cornea in order to reduce the potential for further corneal injury.**³²

Manual retraction of the eyelids with gauze pads does not always allow for adequate irrigation of the conjunctival fornices. Eyelid retractors (e.g., Desmarres retractors or a bent paper clip) must be employed (**Figure 187-4**). **The eye must be well anesthetized when using eyelid retractors and care must be taken to avoid further ocular injury.** Desmarres retractors are preferred to paper clips.

FIGURE 187-3. Standard ocular irrigation setup using intravenous tubing. An assistant retracts the eyelids using gauze pads or eyelid retractors. Complete irrigation of the conjunctival sacs is crucial.

A

B

FIGURE 187-4. Eyelid retractors. **A.** The Desmarres eyelid retractor. **B.** An eyelid retractor fashioned from a paper clip.

Many paper clips are coated with nickel or silver that can flake off and result in iatrogenic foreign bodies.³⁹ The use of a Water-Pik or handheld drench hose has been described but offers no definite advantages over intravenous tubing.^{40,41}

The Morgan Lens (MorTan Inc., Missoula, MT) is a commercially available device that is less labor intensive and facilitates ocular irrigation. It is a scleral contact lens-type device that is designed to fit over the anterior ocular surface (**Figure 187-5A**). Connect the proximal end of the device to intravenous tubing and start a minimal flow of irrigant solution through the Morgan Lens. Retract the upper eyelid and ask the patient to look down. Insert the lens under the upper eyelid (**Figure 187-5B**). Retract the lower eyelid and ask the patient to look upward. Insert the lower part of the lens under the lower eyelid (**Figure 187-5C**). Increase the flow of the irrigant solution through the lens. Remove the lens by reversing these steps (**Figure 187-5D**). The company makes the Medi-Duct to collect the irrigant fluid after it flushes the eye (**Fluid 187-5E**).

The EyeCap (Splash Medical Devices LLC, Atlanta, GA) is a simple device to irrigate an eye (**Figure 187-6**). The unit is quick to set up by just screwing it onto a bottle of sterile saline. The base of the unit has universal threads to attach to a bottle of sterile saline (**Figure 187-6**). The other end is wide and contoured to fit over the orbit. The device allows the saline to deflect off its sidewalls and pool over the eye. The patient can open their eye “under water” to gently allow high-volume eye irrigation. This device cannot be used for foreign bodies embedded in the cornea, for penetrating injuries, or if a ruptured globe is suspected.

Some Emergency Physicians use a nasal cannula for bilateral eye irrigation due to its convenience, low cost, and easy access when

A

B

C

D

E

FIGURE 187-5. Eye irrigation with the Morgan Lens. **A.** The Morgan Lens. **B.** Placement of the lens under the upper eyelid. **C.** Placement of the lens under the lower eyelid. **D.** Removal of the lens. **E.** The Medi-Duct fluid collection system. (Photos courtesy of MorTan Inc., Missoula, MT.)

compared to the Morgan Lens. It is more tolerable for some patients than a Morgan Lens. Cut the nasal cannula tubing close to the branch point to eliminate any dead space. The long length of the tubing is not needed. Connect the proximal end (i.e., the spike) to

the IV fluid bag. Put the cut end of the nasal cannula tubing into the distal end of the IV tubing. Apply tape to the connection to prevent leaks and to prevent the tubing from coming out of the IV tubing. An alternative is to use a nasogastric tube connector to connect the

FIGURE 187-6. The EyeCap device attached to a bottle of sterile saline. (Photo courtesy of Joseph Schultz, MD and BSN Medical Inc.)

two tubings. Place a basin to catch the used irrigation fluid. Cover the area with absorbent pads (i.e., chux) to keep the patient and bed dry. Place the prongs of the nasal cannula on the bridge of the patient's nose. Tape the nasal cannula in place. Put topical anesthesia in the eyes and IV fluid bag. Open the flow from the IV fluid bag wide open to irrigate the eyes.

SOLID PARTICLES

Ocular burns can be caused by chemicals that are primarily in the solid form (e.g., lime). **Attempt to remove as much solid as possible prior to irrigation using a moistened cotton-tipped applicator while evert and retracting the eyelids. Quickly proceed to irrigation once most of the solid material has been removed or if removal is limited by blepharospasm.** Copious irrigation is often successful in removing any residual solid material.²⁴ Proceed directly to irrigation when solid material is not suspected in significant quantity. Inspect the conjunctival sac for foreign material once the initial irrigation has been completed.

CONTACT LENSES

Concern that contact lenses may trap chemicals between them and the cornea appears to be unfounded. **Contact lenses may be protective and act as a shield between the toxin and the cornea.**^{42,43} **Irrigation should not be delayed in order to remove a contact lens unless it appears that a contact lens can be removed easily and quickly (Chapter 186).** This is the case even when using commercial irrigation devices. Contact lenses can be removed once an initial

period of irrigation has been completed. The contact lenses should be discarded as the toxin may be absorbed by the contact lens only to be released onto the surface of the cornea if reused.^{17,42}

IRRIGATION FLUID

The choice of irrigation fluid is much less important than the speed with which irrigation is started.^{26,29} Tap water is perfectly acceptable at the scene of the chemical exposure although there may be problems with patient discomfort.^{24,25} Normal saline and Ringer's lactate solution are both acceptable during ambulance transport and in the Emergency Department. It has been thought that the more neutral pH of Ringer's lactate solution (pH 6.0 to 7.2) should cause less patient discomfort than normal saline (pH 4.5 to 6.0). Similarly, balanced salt solutions (e.g., BSS Plus, Alcon Laboratories, Fort Worth, TX) should theoretically cause less patient discomfort due to their enhanced buffering capacity, physiologic osmolality, and physiologic pH. These theories have yet to be clearly substantiated.^{16,44,45} **Use the irrigant fluid that is most readily available.**²⁵ Balanced salt solutions should be used only in patients who require prolonged irrigation and for whom other irrigants are unsuitable due to their expense and time-consuming preparation (e.g., reconstitution in glass bottles).^{16,44}

The use of warmed irrigation fluid appears to increase patient comfort.⁴⁶ An optimal irrigant temperature is 32.2°C to 37.8°C (90°F to 100°F).⁴⁶ It was found that 120 seconds was required to heat 1 L bags of normal saline and Ringer's lactate solution to a temperature of 101°F in a microwave oven set at the highest cooking intensity.⁴⁷ **This cannot be routinely recommended as microwave ovens vary and overheated irrigant fluid will cause secondary injury. Irrigation should not be delayed while an irrigant fluid is being warmed despite the potential value of warmed fluid.** Commence irrigation with room temperature crystalloid solution and switch to a warmed crystalloid solution once prepared. Cooler liquids at the beginning of irrigation may help reduce the heat of the reaction and limit chemical injury.²⁹ The unproven theory that using a cold irrigant may provide cold anesthesia has been suggested.⁴⁸

There is probably no chemical ocular burn for which crystalloid irrigants are contraindicated.²⁶ Metallic sodium, metallic potassium, and white phosphorus may react violently. Remove any visible solid particles with a cotton-tipped applicator prior to irrigation. Irrigation with copious amounts of crystalloid probably dissipates the heat of the initial reaction more than it initiates a thermochemical reaction.²⁶

SPECIFIC ANTIDOTES

The mainstay of treatment for chemical ocular burns is early and copious irrigation. Specific antidotes usually play little role in the treatment of most toxic ocular exposures. There are some instances where antidotes can be helpful once the initial irrigation has been performed. **Consultation with a poison center or Toxicologist should be considered in cases of exposure to unusual toxins.**³²

EDTA may be helpful in removing adherent calcium hydroxide corneal deposits from lime exposures that cannot be removed with a cotton-tipped applicator or toothless forceps.^{1,12,32} A 0.05 M neutral solution of EDTA can be prepared by diluting 20 mL of Endrate disodium (150 mg/mL) with 180 mL of normal saline.¹² A cotton-tipped applicator soaked in the EDTA solution can be used to loosen such deposits. EDTA may also be useful in exposures to potassium permanganate and zinc chloride.¹²

Ascorbic acid may be useful in potassium permanganate exposures. A 5% solution can be prepared by dissolving a 500 mg tablet of ascorbic acid in 25 mL of normal saline. The resultant manganese oxide deposits can be dissolved by dripping the solution into the eyes from a moistened piece of gauze.⁴⁹

Numerous other miscellaneous antidotes can be used for specific exposures. Copper sulfate in a 3% solution can be used to negate the effects of embedded white phosphorus.^{12,32} Polyethylene glycol may be useful in phenol exposures.⁵⁰ Mineral oil has been suggested in the removal of cyanoacrylates.³² Calcium gluconate solutions have no beneficial effect in ocular exposures to hydrofluoric acid.⁵¹

DURATION OF IRRIGATION

Irrigation should be continued for 20 minutes in the home or workplace prior to patient transport.²⁵ Emergency medical technicians should continue irrigation during ambulance transport until arrival at the Emergency Department.⁵² The duration of any further irrigation in the Emergency Department depends on the severity of the exposure and the nature of the toxin.

Minor exposures with nontoxic substances need not undergo copious irrigation. Irrigation with crystalloid solution using a squeeze-type bottle may be sufficient. Irrigation that had been performed either in the home or in the workplace may be all that is needed. However, treatment should proceed as for caustic agents if the chemical nature of the substance is unknown. **Assume that any previous irrigation was inadequate and that further irrigation is necessary in the Emergency Department.⁴**

No definite standard duration for ocular irrigation is available in the literature. Most would agree that patients who are significantly symptomatic or who have received a caustic exposure should have their eyes irrigated with a minimum of 1 to 2 L of crystalloid solution over 20 to 30 minutes.^{24,53} Exposures to noncaustic agents, milder acid burns, and very mild alkali burns will usually not need further irrigation. Moderate to severe acid burns and anything more than a mild alkali burn will likely require more prolonged irrigation.

The duration of irrigation for caustic exposures is in part governed by pH measurement. After the initial irrigation, measure the pH of the inferior conjunctival sac using wide-range pH paper (i.e., accurate in the pH range of at least 2 to 10) or litmus paper.¹² **Litmus paper with a narrower range and urine dipsticks may not be adequate. If the pH is abnormal, continue irrigation and recheck the pH at 10 to 15 minute intervals until it normalizes.^{12,32}** If the pH has reached the near-normal range (i.e., 7 to 8), discontinue irrigation and recheck the pH in 10 to 30 minutes to ensure that it continues to remain normal.^{26,32} **In clinically severe caustic burns, regardless of the ocular pH, irrigation should be continued until the patient is evaluated by an Ophthalmologist. Alkali burns are more likely to require prolonged irrigation than acid burns.** Several hours of irrigation may be required for severe alkali burns. The Ophthalmologist may opt to perform a regional nerve block to incapacitate the orbicularis oculi muscle to limit blepharospasm and improve patient comfort.¹³

ASSESSMENT

Ocular assessment should be limited to observation of gross injury, assessment of ocular pH, and quick verification of visual acuity until irrigation is complete. These assessments should not be prolonged and should not delay initial irrigation. A full ophthalmologic assessment is required once irrigation has been discontinued. This should include a recheck of visual acuity, measurement of intraocular pressures, and a slit lamp examination to evaluate for corneal injury, uveitis, and globe perforation.

AFTERCARE

The extent of aftercare required is dependent upon the severity of the injury.^{7,19,22,54,55} Minor exposures to innocuous agents and very mild caustic exposures without corneal changes should be reevaluated in 24 hours if the patient is asymptomatic. Some exposures (e.g.,

gases, vapors, and fumes) can result in delayed evidence of corneal injury on slit lamp and fluorescein exams.¹² Patients with apparently minor exposures should be cautioned to return to the Emergency Department if their symptoms worsen or do not improve.

Patients with mild exposures that result in corneal defects should be treated with topical antibiotics that have antistaphylococcal and antipseudomonal activity.¹² Ascertain the patient's tetanus immune status and administer prophylaxis as indicated. Analgesics or an eye patch (Chapter 193) may be offered if patient discomfort is significant.^{1,12} Cycloplegics should be prescribed in order to decrease the pain resulting from ciliary spasm and to decrease the risk of formation of posterior synechiae if anterior chamber involvement is suspected.^{12,37} A patient chronically using phosphate buffer-containing eye drops (e.g., timolol or latanoprost) is at greater risk of corneal calcification after a chemical burn.⁵⁶ Telephone consultation with an Ophthalmologist is recommended. Ophthalmology follow-up should occur within 24 hours.

Moderate to severe ocular burns require admission and acute evaluation by an Ophthalmologist. Medical treatment of secondary glaucoma may be required. Anterior chamber paracentesis (Chapter 190) and lavage may be needed early in the course of severe alkali burns to decrease the anterior chamber pH and intraocular pressure.^{1,12,32,50} Necrotic tissue will have to be debrided.⁴ The goals of longer-term therapy include the prevention of corneal ulceration, prevention of scarring of the anterior ocular structures, prevention of globe perforation, and promotion of corneal reepithelialization.³² Steroids, nonsteroidal anti-inflammatory agents, frequent lubrication, and soft contact lenses may help.^{1,4} Ascorbic acid and collagenase inhibitors are experimental. More severe injuries require surgical intervention due to the loss of stem cells at the limbus and thus the loss of potential corneal reepithelialization.⁴

COMPLICATIONS

Pain and discomfort are common after ocular exposure to chemicals.⁵⁵ These can be minimized with topical ophthalmic anesthetic agents, parenteral sedatives, and parenteral narcotics in the Emergency Department. Corneal injury is usually the result of the primary chemical injury. Corneal injury may result from the irrigant or irrigating device, particularly if improper technique is used. Frequent use of topical ophthalmic anesthetic agents can lead to corneal injury. Extrusion of ocular contents is possible in the setting of a globe penetration. The diving reflex is a rare but possibly significant complication. This reflex is mediated by the ophthalmic branch of the trigeminal nerve and the vagus nerve. It is triggered by a cold water stimulus to the face and results in bradycardia without hypotension. The diving reflex is more common in infants and children. Its clinical importance is greatest in patients with significant comorbid disease. Continuous cardiac monitoring is wise in these patients. Irrigation with warm water may limit this reflex.^{57,58}

SUMMARY

Ocular irrigation is an eye-saving procedure in the setting of significant ocular burns. It is an easy and safe procedure to perform. First-aid workers, emergency medical technicians, and Emergency Department personnel should be trained in its use. Ocular irrigation should be performed rapidly with the most available nontoxic irrigant as delays of even seconds can limit its effectiveness.

Intraocular Pressure Measurement (Tonometry)

Rosalia Mbugua and Adam Jennings

INTRODUCTION

This chapter is designed to assist the Emergency Physician in the decision of when it is necessary to measure intraocular pressure (IOP) and will review several reliable methods of tonometry. There are multiple traumatic, pathologic, and postsurgical causes of changes in IOP. **The clinical signs and symptoms of elevated IOP are similar regardless of the etiology.** Digital palpation is the oldest and simplest form of tonometry and remains useful in select situations. Schiøtz indentation tonometry is discussed for historical purposes and is an accurate method to measure IOP. The nonportable Goldmann or applanation tonometer serves as the standard for measuring accurate IOP. It requires the use of a slit lamp and can be difficult to master. The hand-held Perkins and Kowa tonometers are based on the same principle as the Goldmann and require

experience to use effectively. The electronic Tono-Pen is best known to most Emergency Physicians and is discussed at length. The literature describes the measurement of anterior chamber depth with bedside ultrasound to measure IOP. This may be useful in patients with significant facial trauma and are unable to open their eyes. The Emergency Physician should be comfortable with one or more of these techniques. **The early detection of abnormal IOP can prevent irreversible vision loss.**

ANATOMY AND PATHOPHYSIOLOGY

Aqueous humor is produced by the ciliary body in the posterior chamber of the eye directly behind the iris (**Figure 188-1**). Most of the aqueous humor flows forward through the pupil and into the anterior chamber. It drains out of the eye through the trabecular meshwork located at the angle where the cornea and iris meet. This is the area referred to in open angle, narrow angle, and angle-closure glaucoma. Aqueous humor production is equivalent to outflow in healthy eyes. IOP reflects the pressure of the ocular contents and by convention is expressed in millimeters of mercury or mmHg.¹ **The mean IOP in the general population is 16 mmHg with a standard deviation of 3 mmHg.² Normal pressure ranges from 10 to 22 mmHg.**

Aqueous humor production and outflow can be dramatically affected by disease or injury of the eye. Even small changes in IOP over long time periods can be vision threatening. **Significant increases in the IOP can cause rapid and irreversible damage to vision in just a few hours.** Nontraumatic conditions that result in an elevation of IOP include primary angle-closure glaucoma and secondary angle-closure glaucoma. Traumatic conditions associated with elevated IOP include retrobulbar hemorrhage, hyphema, and traumatic iritis. Conditions associated with low IOP that threaten vision include penetrating trauma and postsurgical complications.

Patients with primary or secondary acute angle-closure glaucoma often present with ocular pain and decreased vision in one eye. They may describe a headache in the brow region, with or without associated nausea and vomiting. External examination frequently reveals that the conjunctiva is erythematous, the cornea appears milky or

FIGURE 188-1. Anatomy of the anterior segment of the eye: (1) anterior segment; (2) posterior segment; (3) ciliary body; (4) trabecular meshwork; (5) cornea; (6) iris.

FIGURE 188-2. High magnification of an eye with angle-closure glaucoma and a markedly elevated IOP. Note the corneal edema and the mid-dilated pupil.

hazy, and the pupil is slightly dilated with a sluggish response to light (**Figure 188-2**).

Traumatic retrobulbar hemorrhage (Chapter 194) can result in markedly elevated IOP. Patients will present with a painful proptosis and fullness of the periorbital tissues. There is usually restricted movement of the eye in one or more fields of gaze. Acute onset of retrobulbar inflammation will present the same way without the history of trauma. A spontaneous nontraumatic retrobulbar hemorrhage can occur in patients with a coagulopathy.

Traumatic iritis may result in an elevated or a reduced IOP. Traumatic iritis presents following blunt, nonpenetrating trauma to the eye. Inflammatory cells circulating in the anterior chamber may impede aqueous outflow resulting in high IOP. Iritis may affect the ciliary body causing a decrease in the production of aqueous humor and a lower IOP. These patients present with eye pain and photophobia. They usually describe their vision as slightly blurred and give a history of trauma within the past 48 hours. The history of recent trauma and light sensitivity is important given that the external examination of the eye may appear normal. The cornea will be clear. **A slit lamp examination is usually necessary to identify the inflammatory cells in the anterior chamber.**

A hyphema is visible blood that layers out in the anterior chamber between the iris and the cornea (**Figure 188-3**). A microhyphema is diffuse blood circulating in the anterior chamber. These patients present with decreased vision, photophobia, and blood in the anterior chamber. A common cause of blood in the anterior chamber is

FIGURE 188-3. A traumatic hyphema with 10% to 15% layered blood in the anterior chamber.

blunt nonpenetrating trauma to the eye. A patient with blood in the anterior chamber and a history of sickle cell disease or trait is at a higher risk of elevated IOP.³ Consult an Ophthalmologist if a sickle cell patient presents with blood in the anterior chamber.

INDICATIONS

Patients presenting with a painful eye, red eye, decreased vision, and no history of ocular trauma should have their IOP measured and documented. Do not measure IOP if there is a history of blunt trauma associated with these symptoms. Some of the common presentations that require documentation of the IOP are reviewed in the previous section. This includes confirming the clinical diagnosis of acute angle-closure glaucoma, determining IOP after blunt ocular trauma, and determining IOP in a patient with iritis.

CONTRAINDICATIONS

It is essential to rule out a ruptured globe before tonometry is performed when a patient relays a history of trauma. Tonometry should be strictly avoided if there is evidence of a ruptured globe or the suspicion of a ruptured globe. A ruptured globe from penetrating trauma to the anterior segment of the eye, including corneal or scleral lacerations, is usually obvious upon clinical examination. **Blunt trauma resulting in a ruptured globe may be very difficult to see on examination. Any blunt force (e.g., closed fist) causing an anteroposterior compression of the globe can result in a scleral rupture posterior to the attachment of the extraocular muscles. This is rarely obvious on external examination or a nondilated slit lamp examination.** The clue is that the patient has dramatically reduced vision and prominent swelling of the periorbital tissues.

Viral conjunctivitis is one of the most common ocular conditions seen in the Emergency Department. Conjunctivitis is so highly infectious that it is a relative contraindication to performing tonometry. These patients may present with ocular pain and decreased vision just like patients with angle-closure glaucoma. Conjunctivitis symptoms are usually binocular and the pain is not as severe. Acute angle-closure glaucoma almost always presents in one eye. It is reasonable to proceed with tonometry to rule out increased IOP as an etiology of a painful red eye if the diagnosis of conjunctivitis is uncertain. **Clean the instrumentation carefully to prevent spreading the infection to the contralateral eye.** The instrument of choice in cases of a suspected infection is a hand-held unit that uses disposable and single-use latex covers for the instrument.

EQUIPMENT

■ TOPICAL OPHTHALMIC ANESTHETIC AGENTS

- Proparacaine hydrochloride 0.5% (e.g., Alcaine, Ocu-Caine, Ophthaine, Ophthetic)
- Tetracaine hydrochloride 0.5% (e.g., AK-T-Caine, Altacaine, Opticaine, Protocaine)

■ TOPICAL STAIN FOR TEAR FILM

- Fluorescein sodium 1 mg strips (e.g., Fluorets, Fluor-I-Strip-AT, Ful-Glo)
- Fluorescein ophthalmic solution (e.g., Fluress, Fluorescein Sodium)

■ TONOMETERS

- Goldmann applanation tonometer (**Figure 188-4**)
- Hand-held applanation tonometer (**Figures 188-5, 188-6, and 188-7**)

FIGURE 188-4. The Goldmann applanation tonometer.

- Schiøtz indentation tonometer (**Figures 188-8 and 188-9**)

■ ANTISEPTIC

- 70% isopropyl alcohol solution and swabs
- 3% hydrogen peroxide solution

FIGURE 188-5. The Icare hand-held tonometers. **A.** The TA01i model. **B.** The il100 model. (Photos courtesy of Icare, Raleigh, NC.)

FIGURE 188-6. The Accutome hand-held tonometers. **A.** The AccuPen model. **B.** The AccuPen Silo model. (Photos courtesy of Accutome Inc., Malvern, PA.)

PATIENT PREPARATION

Inform the patient of the need to measure the pressure in their eye. Explain that an instrument will contact their tear film directly over the cornea. Reassure the patient that tonometry is not painful. It is not necessary to have the patient sign a consent form as tonometry is part of a routine eye examination. One may choose to document the discussion with the patient for completeness.

Remove all contact lenses before the instillation of any topical ocular anesthetic agent or fluorescein. Measuring IOP through a contact lens is unreliable. The fluorescein dye will permanently stain contact lenses and clothing.

Instill one drop of a topical ophthalmic anesthetic agent in both of the patient's eyes. The contralateral eye is used as the control even if only one eye is of concern. Topical ophthalmic anesthetic agents begin working within 30 seconds and remain effective for 10 to 20 minutes. The drops may burn when applied and may cause a transient drying of the cornea. **Instruct the patient not to touch or rub their eyes until the anesthesia wears off.**

Instill fluorescein when using any prism applanation tip such as in Goldmann, Perkins, or Kowa tonometers. Fluorescein is not needed when using the Tono-Pen or the Schiøtz tonometer. Fluorescein is available on strips or in solution. Fluorescein strips are applied to the tear film on the inner layer of each lower eyelid. Dampen the

FIGURE 188-8. The contents of the Schiøtz tonometer case.

strip with a drop of topical anesthetic before application if the eye is extremely dry. The alternative is to instill a drop of fluorescein solution in the cul-de-sac of each lower eyelid.

All plastic prism applanation tonometer heads and the metal plunger of the Schiøtz need to be sterilized to prevent cross-contamination. Do not use sterilization solution on electronic tonometer tips. Use a prepackaged 70% alcohol swab or gauze soaked in 70% alcohol to sterilize the tip of a tonometer. Apply the alcohol to the tip of the prism for 10 seconds and allow it to air dry. Gauze soaked in 3% hydrogen peroxide may also be used. Rinse the tip with sterile saline to wash off the 3% hydrogen peroxide before application to prevent iatrogenic corneal abrasions. These described methods effectively disinfect for common bacteria

and viruses, adenovirus, herpes simplex, and human immunodeficiency virus (HIV).^{4,5} Replace the disposable cover over the tip of the tonometer after each use.

TECHNIQUES

DIGITAL PALPATION

Digital palpation is not as accurate as applanation tonometry. Digital palpation is an informal means of judging IOP. One can use the built-in comparison with the contralateral eye. Studies examining this technique have shown that inexperienced examiners can improve their accuracy with a short training session to within 5 mmHg of the actual IOP 88% of the time.⁶ Digital palpation should not be attempted if there is any potential for a ruptured globe.

Place the patient supine or in a reclined position. Ask the patient to close their eyes and look straight ahead through the closed eyelids. Stand next to the patient's torso and face them. Place the right thumb over the patient's left eye and left thumb over the patient's right eye. Place the remaining fingers of both hands on the patient's temples for stability. Apply gentle alternating pressure to each globe. The Emergency Physician should be able to ascertain any difference in pressure between the two eyes. The Emergency Physician may also gently palpate their own globe as a normal control. This qualitative measurement is often sufficient to determine a significantly elevated IOP.

SCHIØTZ TONOMETRY

The Schiøtz tonometer estimates IOP by measuring the indentation of the globe caused by a known weight.⁷ The Schiøtz tonometer is a sturdy, low-maintenance, and affordable instrument. It is gravity dependent and requires the patient to be supine or have their head fully extended to get an accurate reading. The Schiøtz tonometer case contains the Schiøtz tonometer, a calibration scale, weights, and a calibration platform (Figure 188-8).

FIGURE 188-9. The Schiøtz tonometer. A. Schematic of the tonometer. B. Schematic of the plunger assembly.

The tonometer consists of a plunger and a hammer device connected to a needle (**Figure 188-9**). The needle is calibrated to a scale with each unit measuring 0.05 mm on the scale. The plunger, the hammer, and the needle weigh 5.5 gm. This can be increased to 7.5 gm, 10 gm, or 15 gm by adding known weights to the tonometer. The weighted plunger is heavy and has a large contact area that causes significant indentation of the cornea with each measurement. **The more weight it takes to move the needle on the scale or indent the cornea, the higher is the IOP.** The scale reading is converted to IOP in mmHg by a conversion chart supplied with each Schiøtz tonometer (**Figure 188-8 and Table 188-1**).

Place the patient supine or sitting with their head fully extended. Ensure that the patient is comfortable. A tight collar, flexed neck, breath-holding, squeezed eyelids, looking toward the nose, or accommodation results in a falsely elevated reading. Place two drops of a topical ophthalmic anesthetic agent onto each eye.

TABLE 188-1 The Schiøtz Tonometer Scale*

Tonometer reading	5.5 gm load	7.5 gm load	10 gm load	15 gm load
0.0	41.5	59.1	81.7	127.5

18.5				6.2
19.0				5.6
19.5				4.9
20.0				4.5

*Use the tonometer scale reading and the weight applied to the plunger (gram load) to determine the IOP reading in mmHg.

Calibrate the tonometer by placing the footplate of the plunger on the platform provided in the case (**Figures 188-8 and 188-9**). **The scale reading must be “0” while the footplate is on the platform. The instrument requires repair if it does not read zero while on the platform.**

Instruct the patient to look at a fixation target directly overhead and to open both eyes as wide as possible. Spread the eyelids with the nondominant index finger and thumb if necessary. Grasp the Schiøtz tonometer by its handle. **Ensure that the fingers holding the eyelids open are pushing on the orbital rim and not the globe falsely elevating the IOP.** Place the footplate of the Schiøtz tonometer directly over the pupil and gently lower it onto the tear film (**Figure 188-10**). Note the reading on the scale. Add more weight if the scale reading is less than 3 units. **Do not push down on the cornea with the Schiøtz tonometer. This will cause a false elevation in the IOP reading.** Repeat the measurement several times or until three readings are within 0.5 scale units. Convert the scale reading to IOP with the conversion chart (**Table 188-1**).⁸

Clean the tonometer immediately after each use.⁹ Clean the barrel with two pipe cleaners, the first soaked in 70% isopropyl alcohol and the second one dry. Clean the plunger with an alcohol swab.

FIGURE 188-10. The Schiøtz tonometer positioned on the cornea.

Allow the instrument to air dry 1 to 2 minutes before being used in the contralateral eye so that the alcohol evaporates and is not transferred to the corneal surface.¹⁰

GOLDMANN (APPLANATION) TONOMETRY

The Goldmann tonometer is most used by Ophthalmologists and considered the clinical standard for measuring IOP (Figure 188-4).^{11,12} Many use the “old fashioned” dial-type Goldmann tonometer. Some are using the newer digital readout Goldmann tonometer. This method of tonometry is based on the Imbert-Fick principle.¹³ It states that the pressure inside an ideal dry, thin-walled sphere equals the force necessary to flatten its surface divided by the area of the flattening ($P = F/A$; where P = pressure, F = force, and A = area). IOP is proportional to the pressure applied to the eye and the thickness of its walls. The Goldmann tonometer determines the force necessary to flatten or applanate an area of the cornea 3.06 mm in diameter. The degree of flattening is determined while viewing the cornea through a split prism device in the tonometer head and represented by the two semicircles. Fluorescein is used to stain the tear film to distinguish the cornea from the tear film. The eye is viewed through the cobalt blue filter causing the fluorescein stained tear film to appear yellow-green. Inadequate fluorescein stain can affect the tonometer reading. The technique is described below.⁵

The Goldmann tonometer is not portable. It requires the patient to be cooperative, the patient to sit upright, and a working knowledge of the slit lamp. The Goldmann tonometer in combination with a slit lamp examination provides the clinician with the most detailed information about the patient’s ocular condition.

Place two drops of a topical ophthalmic anesthetic agent onto each eye. Place fluorescein dye in the eye. Position the tonometer head and cobalt filter on the slit lamp. Set the tension knob to 10 mmHg. It is more accurate to measure IOP by increasing rather than decreasing the force of applanation. Seat the patient in front of the slit lamp. Support the patient’s chin in the chin rest and place their forehead firmly against the strap. Instruct the patient to look straight ahead and open both eyes as wide as possible. Spread their eyelids with a thumb and forefinger if necessary. **Do not put pressure on the globe while holding the eyelids open.**

Move the tonometer head within one-half inch of the cornea (Figure 188-11). Use the control stick on the slit lamp to center the

FIGURE 188-11. A patient positioned in the slit lamp with a Goldmann tonometer in position to be advanced onto the cornea.

FIGURE 188-12. Semicircles as seen through the Goldmann tonometer. **A.** The inner edges of the semicircles are touching signifying the correct IOP reading. **B.** Semicircles are not touching because the pressure reading on the tension knob is too low. **C.** Semicircles are overlapping because the pressure reading is too high.

applanation head directly over the pupil. Look for two semicircles on the ocular surface as the tonometer head is advanced onto the corneal tear film (Figure 188-12). Ensure that the tension knob is set at 10 mmHg. The semicircles will not be touching if the patient’s pressure is above 10 mmHg (Figure 188-12B). Turn the tension knob clockwise to raise the reading and counterclockwise to lower the reading. Turn the tension knob up until the inside borders of the fluorescein rings are touching (Figure 188-12A). Read the IOP on the tension knob. The semicircles will overlap if the pressure is below 10 mmHg (Figure 188-12C). Turn the tension knob down until the inside borders of the fluorescein rings are touching (Figure 188-12A). Read the IOP on the tension knob.

Clean the tonometer head with an alcohol swab immediately after use. Let it air dry 1 to 2 minutes so that the alcohol evaporates and is not transferred to the corneal surface. Repeat the procedure on the contralateral eye.

HAND-HELD TONOMETRY

The Tono-Pen XL and the Tono-Pen Avia (Figures 188-7B and 188-7C) are lightweight, are simple to operate, and can record IOP with the patient in any position.¹⁰ The small contact area is useful in patients with eyelid swelling and corneal surface irregularities. The Tono-Pen calculates IOP using a strain gauge that creates an electronic signal as the 1.5 mm footplate flattens the cornea.¹⁰ A single microprocessor chip analyzes each application of the footplate and averages 4 to 10 valid measurements to form one reading. The instrument should be stored in its case when not in use. An Ocu-Film cover should remain over the tip when it is stored and changed with each new patient. **The Ocu-Film covers are made of latex. Ask the patient about latex allergies prior to using this device. The tip of the Tono-Pen is very sensitive, is easily damaged, and should never be touched.**

The Tono-Pen XL unit is internally calibrated. The instrument calibration should be checked before the first use each day or in the event of unanticipated readings. Calibration should also be performed whenever it is indicated by the LCD display, when batteries are replaced, or after unsuccessful calibration. **It needs to be calibrated if the word “bAd” appears in the LCD window.** The Tono-Pen is not used or calibrated daily in the Emergency Department. **It is necessary to check the calibration prior to each use.**

The display of “Good” in the LCD window indicates that the Tono-Pen is functioning properly. Press the operation button once. The Tono-Pen will display [8.8.8.8] in the LCD window, followed by a single row of dashes [----], and then a double row of dashes [= = =]. This indicates that the Tono-Pen is ready to measure IOP.

To calibrate the Tono-Pen, aim the transducer end straight down. Depress the operation button twice within 1.5 seconds. The Tono-Pen will beep and display “CAL” in the LCD window. Wait for the Tono-Pen to beep and display “UP” in the LCD window. This can take up to 15 seconds. Immediately and quickly invert the Tono-Pen so that the transducer end is pointing straight up. The Tono-Pen

FIGURE 188-13. The Tono-Pen positioned in front of the cornea.

will beep and display “Good” in the LCD window if it is functioning properly. Repeat the calibration procedure if “bAd” is displayed in the LCD window.

Place the patient in a seated or supine position. Instruct the patient to look straight ahead. Place two drops of a topical ophthalmic anesthetic agent onto each eye. Fluorescein is not necessary when using the Tono-Pen. Grasp the Tono-Pen like a pencil and hold it perpendicular to the corneal surface (**Figure 188-13**). Gently contact the cornea directly over the pupil or central cornea. **Contact the cornea in a series of light taps. The Tono-Pen should not indent the cornea if used properly, reducing the risk if there is an unidentified ruptured globe or a hyphema.** The Tono-Pen chirps each time a valid IOP measurement is obtained. The micro-processor sounds a final beep after it receives four valid readings. The mean IOP will be displayed in the LCD window. A single row of dashes [----] indicates that an insufficient number of valid readings were collected. Obtain additional measurements after pressing the operation button.

REBOUND TONOMETRY

The unit(s) used in the Emergency Department are the Icare devices (**Figures 188-5A and 188-5B**).^{14,15} The Icare tonometers (Tiolat Oy, Helsinki, Finland) use a smaller zone to indent the cornea, do not require fluorescein, and do not require topical anesthesia.¹² There are numerous other advantages including no risk in using latex, no device calibration, preferred by patients, quick IOP measurement, and comparable to application tonometry. The Icare tonometer is useful for the Emergency Department. It uses disposable and single-use probes. The tip of the probe is rounded to minimize damage to the cornea. The lightweight probe is propelled toward the cornea, bounces back off the cornea and to the device, and the unit detects deceleration. The movement of the probe induces a voltage change that is converted to a magnetic field that is detected by the device. There is also a device for home use by the patient.^{16,17} The home device records the IOP measurement, date taken, and time taken. The information can be uploaded to a computer and sent to the Ophthalmologist. The units are reliable, easy to use, and provide frequent IOP measurements during daily activities. The devices have been used in young children.¹⁸

ALTERNATIVE DEVICES

There are many additional hand-held tonometers of varying cost, ease of use, and availability. The Perkins MK-2 (Haag-Streit, Essex, United Kingdom) and the Kowa HA-2 (Kowa Optimed, Inc.,

FIGURE 188-14. The Pulsair IntilliPuff. (Photo courtesy of Keeler, Brownhill, PA.)

Torrance, CA) are two hand-held tonometers using the Goldman prism technique (i.e., aligning the semicircular images). They are portable but require a familiarity with Goldman applanation. The Accupen (Accutome, Malvern, PA) is like the Tono-Pen with a few differences. These include ease of use and longer battery life. In addition, it does not require calibration before every use. The Diaton transpalpebral hand-held tonometer (Bicom Inc., Long Beach, NY) is designed to measure IOP through a patient's closed eyelids.¹¹ Another transpalpebral tonometer is the phosphene tonometer, the Proview Eye Pressure Monitor (Bausch & Lomb, New York, NY). Both transpalpebral tonometers can be used at home by patients. Unfortunately, both transpalpebral units do not correlate with applanation tonometry and have limited clinical use. The Pulsair IntilliPuff (Keeler, Brownhill, PA) is the only portable, hand-held, noncontact tonometer (**Figure 188-14**). This unit may be valuable to measure the IOP if a globe rupture is suspected.¹⁹

Measuring anterior chamber depth with bedside ultrasound is another alternative.²⁰ The patient's closed eye is covered with a Tegaderm and ultrasound gel is applied over the Tegaderm. Assess the anterior chamber using a high-frequency transducer. The anterior chamber depth is measured in the transverse and sagittal planes by measuring the widest depth between the anterior edge of the lens and the cornea.²⁰ This measurement is compared to the unaffected eye.

A final device is the Sensimed Triggerfish Contact Lens Sensor (Sensimed AG, Lausanne, Switzerland).^{16,21-23} The Contact Lens Sensor is used by Ophthalmologists for outpatient monitoring of IOP. It consists of the lens and the monitoring system (**Figure 188-15**). The Contact Lens Sensor uses two titanium-platinum wire loop strain gauges to detect deformation of the cornea and sclera that corresponds to volume changes of the eye and thus IOP. The Contact Lens Sensor takes an IOP measurement every 5 minutes and provides 288 readings over 24 hours.

AFTERCARE

No aftercare is specific to the technique used to measure IOP. Instruct the patient, if using topical ocular anesthetic, to not rub their eyes until the anesthetic wears off. The fluorescein can stain

A

B

FIGURE 188-15. The Sensimed Triggerfish tonometry system hand-held tonometers. **A.** The contact lens. **B.** The system on a patient consists of the contact lens (1), the antenna around the eye (2), the thin flexible cable (3), and the recorder (4). (Photos courtesy of Sensimed AG, Switzerland.)

clothes and contact lenses. Do not replace contact lenses until the fluorescein wears off and instructed it is safe depending on the underlying eye condition. The device needs to be cleaned and sterilized after used on a patient.^{9,24} Follow the hospital and device manufacturer's recommendations. The routine maintenance of the

device is beyond the scope of this chapter.²⁴ Refer to the device manufacturer's recommendations.

ASSESSMENT

The normal range for IOP is 10 to 22 mmHg. A baseline IOP is specific to each patient and the patient's contralateral eye can serve as a control. We can make general assumptions about certain ranges of IOP to make rapid clinical assessments and facilitate patient care. Readings of 0 to 9 mmHg should be discussed with an Ophthalmologist, especially if there is a history of recent eye surgery or recent eye trauma. Readings of 10 to 21 mmHg are normal. Readings of 22 to 25 mmHg should be followed up with an Ophthalmologist within 2 to 3 days. IOP readings greater than 26 mmHg require an emergent consultation with an Ophthalmologist.

COMPLICATIONS

Infectious agents can be transferred via tonometer heads.¹³ **It is essential to properly clean each instrument before use, before using it on the contralateral eye, and after use.** The use of a 70% isopropyl alcohol swab is an effective disinfectant for the Goldmann and Schiøtz tonometers. The Tono-Pen has single-use disposable latex covers.

Incorrect IOP measurements can occur for a variety of reasons. An improperly working plunger on the Schiøtz tonometer can result in falsely low measurements. IOP will be elevated if measured while the examiner's hand is holding the eyelids open and inadvertently pressing on the underlying globe. Measurement during eye movements, blinking, or eyelid movements will elevate IOP. Maneuvers that increase intracranial pressure (e.g., Valsalva or breath-holding) also increase IOP.

Corneal abrasions can occur while using contact tonometers. It is very important to have a cohesive tear film to avoid corneal abrasions. Instruct the patient to blink several times just prior to tonometry to spread the tear film. Apply artificial tears in patients with extremely dry eyes. The Schiøtz tonometer puts significant weight on the cornea and must be applied very gently. Warn the patient that their eye may be uncomfortable when the anesthetic wears off if a small abrasion is suspected after measuring the IOP. Instruct the patient to instill artificial tears every 4 to 6 hours. Treat larger abrasions with a topical ocular antibiotic of choice and schedule a follow-up visit.

FUTURE CONSIDERATIONS

The future for Ophthalmologists related to IOP monitoring shows several developments. Ambulatory IOP monitoring may be common.²⁵ The treatment of IOP may use drug-eluting ocular contact lenses.^{26,27} These were approved by the U.S. Food and Drug Administration in early 2016. Patients using these devices will present to the Emergency Department when they experience problems or after office hours.

SUMMARY

The practice of tonometry is essential in guiding appropriate eye care. The Goldmann, Tono-Pen, Schiøtz, or Icare contact tonometers are readily available in most Emergency Departments. The literature frequently debates the comparative accuracy of each instrument. The Goldmann applanation tonometer is generally considered the clinical standard. All three instruments are useful for screening IOP in the Emergency Department. Factors such as the patient's ability to ambulate and the presence of periorbital swelling

will influence the choice of an instrument. The Emergency Physician should select a tonometer that feels comfortable and use it routinely. The Emergency Physician will be able to measure IOP rapidly and reliably with repeated use of the tonometer.

Digital Globe Massage

Carlos Roldan and Eric F. Reichman

INTRODUCTION

Digital globe massage has been considered a heroic measure to salvage vision in cases of central retinal artery occlusion (CRAO), an ophthalmologic emergency.¹⁻¹¹ CRAO is one of several diagnoses to consider in the patient with acute painless loss of vision or a visual field. The typical patient is older, between the ages of 50 and 80 years of age, and with significant systemic illnesses. CRAO is most likely an embolic event secondary to atherosclerotic disease. The vision loss is sudden, monocular, and painless. The outcome for CRAO is poor if treatment is delayed more than 2 hours. Spontaneous remission and recovery of visual function are rare. This condition requires an emergent consultation with an Ophthalmologist for medical management and the consideration of an anterior chamber paracentesis (Chapter 190). Digital globe massage can be used in an attempt to relieve the obstruction or break up the embolus so it moves distally to open some blood flow to the retina.

ANATOMY AND PATHOPHYSIOLOGY

The ophthalmic artery is a branch of the carotid artery (**Figure 189-1**). The first branch of the ophthalmic artery is the central retinal artery. This vessel runs along the optic nerve and enters the optic nerve. The central retinal artery is the main blood supply to the retina. The macula has an independent blood supply from other branches of the ophthalmic artery. An area between the macula and the optic nerve receives collateral circulation from the central retinal artery and the ciliary arteries in a small percentage of the population. This explains why a patient with a complete CRAO may have a normal-appearing macula and occasionally an area of perfusing retina adjacent to the optic nerve area.

The individual etiology remains unclear in many cases. Certain etiologies are more likely depending on the patient's age. The main cause of retinal arterial occlusions is an embolic event lodging in the central retinal artery where it narrows to pass through the lamina cribrosa or in a smaller distal branch arteriole. The embolism may be composed of aggregated fibrin and platelets arising from an ulcerated vessel wall thrombus, cholesterol from an ulcerated carotid artery plaque, material from cardiac valvular disease, or thrombus formation from giant cell arteritis in those over 70 years of age. The embolus may also result from an invasive procedure such as cardiac angioplasty, carotid angioplasty and stenting, or a carotid endarterectomy. Consider cardiac valvular disease in those under 40 years of age. Abnormal cardiac rhythms are considered an etiology for intracardiac blood clot formation in all age groups. These may embolize and lodge in the ophthalmic artery or distally in one of the branch arteries. Retrobulbar masses (e.g., a hematoma, neoplasm, or retrobulbar injection) may also lead to an optic nerve and central retinal artery compression.¹

PHYSICAL EXAMINATION FINDINGS

The patient may display vision compromise ranging from a small visual defect to a decreased ability to finger count or perceive light to complete blindness. Grossly, the eye appears normal. However, an afferent pupillary defect may be evident with little or no reaction to direct light and a normal reaction to consensual light. The initial funduscopic examination may show a near-normal retinal appearance (**Figure 189-2A**). This soon progresses to a pale retina,

FIGURE 189-1. The anatomy of the eye. (Used with permission from Riordan-Eva P,Whitcher JP (eds): *Vaughan & Asbury's General Ophthalmology*, 17th ed. McGraw-Hill, 2008.)

bloodless or attenuated arterioles, and “boxcar” segmentation of the retinal veins (**Figure 189-2B**). The fundoscopic exam will then reveal a milky and edematous retina with a cherry-red macula if the entire central retinal artery is occluded. If the cilioretinal artery flow is not occluded, there will be an area of perfusion between the optic disk and the macula (**Figure 189-2B**). An embolus may be visible in the vasculature of the optic disk in rare cases. If a branch retinal artery is occluded, an embolus may be visible in the vessel with ischemia and infarction distal to the occlusion.

It has been shown experimentally that the retinal damage is irreversible after 100 minutes of nonperfusion.³ There is anecdotal evidence that heroic measures to salvage vision after a CRAO have sporadically resulted in the return of vision. A large study showed that the average final visual acuity in patients with a CRAO treated with heroic measures compared to those untreated was only a one-quarter line improvement in Snellen chart visual acuity. If the underlying cause of the CRAO is giant cell arteritis, up to 10% of the cases progress rapidly to bilateral vision loss if the arteritis is left untreated.

Hedges III, MD.

MEDICAL MANAGEMENT

Various methods have been employed to reduce intraocular pressure or to dilate the artery in an attempt to facilitate dislodgement of the embolus.¹⁻¹¹ None of these have been proven to be of benefit in the management of a CRAO.⁶ On the other hand, none of these have been proven to be harmful. Thus, they may prove to be useful in saving the patient's vision. The following interventions should be considered as co-adjuvants to digital globe massage. Oral nitrates (0.5 or 0.4 mg nitroglycerin pills or spray) may vasodilate the retinal artery. Instruct the patient to breathe into a paper bag to increase blood carbon dioxide levels and induce vasodilation. If available, administer carbogen (95% oxygen and 5% carbon dioxide) by face mask instead of using the paper bag.¹¹ Oral and intravenous carbonic anhydrase inhibitors (500 mg Diamox or acetazolamide, respectively) will reduce intraocular pressure and decrease ophthalmic arterial vascular resistance to forward flow.^{1,11} Intravenous mannitol (1 gm/kg of a 20% solution) may cause intraocular fluid to exit the eye and decrease intraocular pressure.^{1,11} Hyperbaric oxygenation treatment can compensate to prevent retinal hypoxemia and ischemia in some cases while awaiting the restoration of arterial flow.³ Intra-arterial fibrinolysis with urokinase or recombinant tissue plasminogen activator (rTPA) can be successful in improving vision and shows promise.^{1,5}

INDICATIONS

Digital globe massage can be performed in cases of CRAO where medical management is contraindicated or not successful. It can also be performed simultaneously with medical management. Treat the patient if they present to the Emergency Department within 24 hours of symptom onset.⁷ It should be performed ideally within 90 minutes of the CRAO.

CONTRAINDICATIONS

Digital globe massage is contraindicated if the patient has had ocular surgery. Consult an Ophthalmologist in these cases before performing the procedure. Use caution if the patient is taking antiplatelet or anticoagulant drugs as they have a higher chance of intraocular bleeding with digital globe massage.⁹ Consider discussing this with an Ophthalmologist first. Otherwise, there are no contraindications to digital globe massage in a nontraumatic CRAO. Digital globe massage is contraindicated if there is the possibility of a perforated globe.

EQUIPMENT

No special equipment is required to perform a digital globe massage.

PATIENT PREPARATION

Perform a funduscopy examination and visual acuity testing.¹⁰ Perform intraocular pressure testing if no contraindications (Chapter 188) exist.¹⁰ Document these results in the medical record. Explain the procedure, its risks, and benefits to the patient and/or their representative. This potentially vision-saving procedure should not be delayed. Verbal consent is adequate; document the conversation in the medical record. Place the patient supine or in a reclining position.

TECHNIQUE

Stand next to the patient's torso and facing them. Instruct the patient to tightly close the eyelids of the affected eye. Place the dominant thumb over the patient's eyelids. Apply firm and steady pressure

with the thumb for approximately 5 seconds. Abruptly release pressure by quickly lifting the thumb off the eyelids. Repeat the procedure several more times as needed.²

ASSESSMENT

Immediately perform a repeat funduscopy examination, intraocular pressure measurement, and visual acuity testing. Document and compare these to the preprocedural evaluations. It should be noted that the funduscopy examination may show improvement while the visual acuity has changed very little or not at all. The intraocular pressure should be decreased if the arterial obstruction is relieved or broken up and moved to smaller (i.e., more distal) arterioles.¹⁰ Depending on the ischemic time, visual acuity may never improve. Repeat the digital globe massage if there is little or no improvement in the funduscopy examination. If significant improvement is noted, the procedure may be repeated in the hope of further improvement.

AFTERCARE

All patients must be evaluated by an Ophthalmologist in the Emergency Department. If one is not available, consider transferring the patient to another facility to be evaluated by an Ophthalmologist. These patients require inpatient admission for further evaluation and management.

Patients with a CRAO usually have significant comorbidities such as hypertension, atherosclerosis, or diabetes. These patients are at risk for additional morbidity and require prompt medical referral to determine the etiology of the CRAO. Medical testing should include blood pressure evaluation, carotid ultrasonography, electrocardiography, echocardiography, blood glucose management, lipid and cholesterol testing, and hyperviscosity studies.¹¹ Any irregularities or abnormal studies will require further evaluation. Patients over the age of 60 need an immediate erythrocyte sedimentation rate (ESR) test in consideration of the possibility of giant cell arteritis.

COMPLICATIONS

If properly performed, digital globe massage has few immediate complications. Overvigorous digital globe massage can result in a lens dislocation or a ruptured globe.⁴ Mechanical trauma can result in injury to the cornea, retinal detachments, and intraocular hemorrhage (e.g., hyphema and intravitreal hemorrhage).

SUMMARY

A CRAO is a true ophthalmologic emergency. The patient will present with sudden, painless, and unilateral loss of vision. Immediate management is required in an attempt to restore the patient's vision. This includes medical management, anterior chamber paracentesis, and digital globe massage. These techniques attempt to reduce intraocular pressure or break up the embolus in order to allow the embolus to move downstream and restore at least partial blood flow to the retina. Despite these interventions, the patient's vision may not recover.

Anterior Chamber Paracentesis

Rene Pineda Carizey

INTRODUCTION

Anterior chamber paracentesis is the removal of fluid from the anterior chamber. The anterior chamber is the area just anterior to the iris and lens and immediately posterior to the cornea. Although not often formally taught or performed in the Emergency Department, an anterior chamber paracentesis is a quick, simple, and safe procedure with important diagnostic and therapeutic roles.¹⁻²⁸ The long-term prognosis is directly related to the duration of symptoms for disease states that present with increased intraocular pressure (IOP) such as acute closure glaucoma and central retinal artery occlusion. In a sense, “time is eye.” The Emergency Physician should become familiar with this technique. Its use can potentially prevent irreversible vision loss, especially when medical management is not sufficient in lowering IOP.

ANATOMY AND PATHOPHYSIOLOGY

The eye is a fluid-filled closed system with a one-way valve. Aqueous humor is produced by the ciliary body and flows from the posterior chamber to the anterior chamber. The aqueous humor from the anterior chamber travels through a fine trabecular meshwork at the anterior chamber angle (i.e., the one-way valve) and leaves via the canal of Schlemm.

IOP normally measures between 10 and 21 mmHg. This represents the balance between the production and outflow of aqueous humor.³ Tonometry is used to measure IOP (Chapter 188). An increase in aqueous humor production, resistance to the outflow of aqueous humor, or additional fluid (e.g., pus or blood) in the eye can severely increase IOP and potentially cause permanent visual loss due to ischemia. Removing fluid via an anterior chamber paracentesis, in addition to medical therapies, will reduce IOP to help prevent further ischemia.

Central retinal artery occlusion (CRAO), usually from an atherosclerotic embolic event, is another potential cause of visual loss that may benefit from an anterior chamber paracentesis in combination with digital ocular massage (Chapter 189) and medical management.^{4,21} Decreasing IOP increases retinal perfusion in attempts to propagate the embolus distally and minimize the amount of visual loss. Traumatic retrobulbar hemorrhages and

other nonintraocular causes of elevated IOP do not benefit from an anterior chamber paracentesis.

INDICATIONS

An anterior chamber paracentesis will immediately reduce IOP but is not a treatment that resolves the underlying cause of the elevated IOP. Medical management is usually initiated first to lower IOP before attempting an anterior chamber paracentesis. An anterior chamber paracentesis is indicated whenever elevated IOP threatens visual loss and medical management is not successful in lowering IOP. Reducing the IOP acutely with an anterior chamber paracentesis in disease states such as acute angle-closure glaucoma, uveitis, hyphema, central retinal artery occlusion, and suppurative endophthalmitis may help prevent further irreversible vision loss if used in conjunction with other medical modalities.^{5-7,23}

There are numerous nonemergent indications for an Ophthalmologist to perform an anterior chamber paracentesis. Diagnostically, an anterior chamber paracentesis can be used for aqueous humor sampling for a suspected infection, lymphoma, and intravitreal drug level injections and monitoring.^{8,9,26,27} It is also performed for isotonic saline injection for flattened anterior chamber reformation and numerous ophthalmologic surgical procedures.

CONTRAINDICATIONS

There are no absolute contraindications to performing an anterior chamber paracentesis since the patient's vision is at risk. Consult an Ophthalmologist prior to the procedure if a ruptured globe is suspected. Relative contraindications include uncooperative patients, patients with allergies to topical ocular anesthetics, and if the Emergency Physician is not comfortable performing the procedure. The patient's airway, breathing, hemodynamic status, and other life-threatening events should always be addressed prior to the procedure.

EQUIPMENT

- Sterile povidone iodine solution
- Topical ophthalmic anesthetic drops, e.g., 0.5% proparacaine or tetracaine
- Broad-spectrum topical antibiotic eye drops, e.g., fluoroquinolone
- Sterile saline minim
- 15° super sharp microblade
- 1 mL tuberculin syringe
- 27 to 30 gauge, 5/8 inch needle^{1,8,11,12}
- Slit lamp

PATIENT PREPARATION

Explain the risks, benefits, and potential complications of the procedure to the patient and/or their representative. Obtain a signed procedural consent and place it in the medical record. Reassure the patient that a “pressure sensation” might be felt during the procedure but they should not experience pain.

Remove all contact lenses prior to placing any topical ocular medications or using fluorescein. **Perform a visual acuity assessment (Chapter 185) and an IOP measurement (Chapter 188) prior to any intervention to document the patient's baseline status and for serial comparisons after the procedure.** Administer a tetanus booster intramuscularly if the patient's tetanus status is unknown or their last tetanus booster has been greater than 10 years. Administer antiemetic and pain medication if the patient is symptomatic.

Retching and vomiting increase IOP and complicate the procedure. Instill one to two drops each of the topical ophthalmic anesthetic and the broad-spectrum ophthalmic antibiotic onto the affected eye. Some Ophthalmologists instill two drops of sterile povidone iodine solution onto the cornea followed by the topical ophthalmic anesthetic drops to dilute it.^{17,18,20,22} Place the patient comfortably in a chair. Position their chin on the slit lamp chin rest. Attempt to comfortably immobilize the patient's head. Use an assistant if needed. Check for proper anesthesia by softly brushing the cornea with a cotton-tipped swab or rechecking IOP.

TECHNIQUES

Numerous techniques have been described to perform an anterior chamber paracentesis. The quickest, simplest, and easiest to perform are the hypodermic needle and saline minim techniques. The surgical technique is often performed by an Ophthalmologist.

HYPODERMIC NEEDLE TECHNIQUE

Anesthetize the cornea and position the patient in the slit lamp. Arm a tuberculin syringe with a 27 to 30 gauge needle. Slightly withdraw the plunger to break the bead on the syringe. Position the tip of the needle at the limbus, somewhere between the 4 o'clock and 8 o'clock position (**Figure 190-1A**). **Gently insert the needle through the cornea and angled anteriorly.** This will ensure that the tip of the needle will enter the anterior chamber and not injure the ciliary body, iris, or lens (**Figure 190-1B**). The anterior chamber holds approximately 0.3 mL of fluid. Slowly withdraw the plunger and aspirate 0.1 mL of fluid from the anterior chamber. Withdraw the needle. Apply topical ophthalmic antibiotic drops immediately after the procedure.

SALINE MINIM TECHNIQUE

A saline minim attached to a hypodermic needle is an alternative to using a syringe (**Figure 190-2**). This technique is simpler to perform when compared to using a hypodermic needle.^{11,12,15} A saline minim is a single-use, soft-sided, disposable container containing 0.5 mL of sterile saline.

Anesthetize the cornea and position the patient in the slit lamp. Prepare the minim. Twist off and discard the tip of the minim. Firmly apply a 27 to 30 gauge needle to the open end of the minim. Grasp the needle-minim unit with the thumb and index finger of the dominant hand. Gently squeeze the minim until one drop of

FIGURE 190-2. The saline minim technique.

sterile saline is expressed from the tip of the needle. Do not release pressure on the sides of the minim. Position the tip of the needle at the limbus, somewhere between the 4 o'clock and 8 o'clock position (**Figure 190-2**). **Gently insert the needle through the cornea and angled anteriorly.** This will ensure that the tip of the needle will enter the anterior chamber and not injure the ciliary body, iris, or lens. Slowly open the thumb and index finger to release the compression on the minim. The aqueous humor will flow from the anterior chamber into the minim. **Do not withdraw enough fluid to dimple the cornea.** Withdraw the minim until the needle exits the eye. Apply topical ophthalmic antibiotic drops immediately after the procedure.

SURGICAL TECHNIQUE

Anesthetize the cornea and position the patient in the slit lamp. Position the tip of the 15° super sharp microblade at the limbus, somewhere between the 4 o'clock and 8 o'clock position. **Gently insert the blade through the cornea and angled anteriorly.** This will ensure that the tip of the blade will enter the anterior chamber and not injure the ciliary body, iris, or lens. Withdraw the blade. Carefully and gently insert a 27 to 30 gauge needle on a tuberculin syringe through the incision. Aspirate 0.1 mL of fluid from the anterior chamber and withdraw the needle. As an alternative, a 27 to 30 gauge needle on a saline minim can be used. Apply topical ophthalmic antibiotic drops immediately after the procedure.

FIGURE 190-1. The hypodermic needle technique. **A.** The needle is inserted obliquely at the limbus. **B.** Transverse view of the eye. The needle enters the cornea at the limbus and is directed anteriorly into the anterior chamber.

ASSESSMENT

Immediately perform an IOP measurement with the same device used before the procedure to measure IOP. The IOP and symptomatic complaints should significantly decrease after the anterior chamber paracentesis procedure. Perform serial IOP measurements every 30 minutes for 2 hours to assess for any recurrence of elevated IOP. Perform and document a postprocedure visual acuity. Readress any symptomatic complaints of eye pain, nausea, and headache. Significant decreases in IOP have been shown immediately and up to 2 weeks after an anterior chamber paracentesis with near resolution of symptoms.^{5,6,19}

AFTERCARE

An Ophthalmologist should evaluate the patient in the Emergency Department if an anterior chamber paracentesis was performed. Immediate surgical intervention may be indicated if there is no improvement in symptoms or the IOP is persistently elevated despite medical management and an anterior chamber paracentesis. Patients can usually be safely discharged home once symptoms resolve and the IOP has normalized. Arrange close follow-up with an Ophthalmologist within the next 24 to 48 hours. Patients are typically discharged with broad-spectrum topical ophthalmic antibiotics, oral pain medications, oral antiemetics, and other antiglaucoma medications (e.g., oral acetazolamide, topical ophthalmic beta-blockers, ophthalmic pilocarpine, and/or ophthalmic steroids).^{10,15} The consulting Ophthalmologist will determine the proper medical management (i.e., the medications, their strength, and the frequency of administration). The patient should immediately return to the Emergency Department if they develop increased eye pain, severe nausea and/or vomiting, or any visual disturbances (e.g., decreased vision, photophobia, halos around lights).

COMPLICATIONS

Mechanical injury to ocular structures (e.g., ciliary body, corneal abrasions, iris, or lens), decompressive retinopathy, infection, and bleeding compose the most serious complications after an anterior chamber paracentesis.^{13,14,25} Inadvertent injection of air into the anterior chamber occurs. This is typically a small amount and resolves spontaneously.¹² Allergic reactions to any of the medications used can also occur.

SUMMARY

Many types of disease pathologies can acutely elevate IOP and result in potential irreversible vision loss. Immediate reduction of the IOP by using medical treatments in conjunction with an anterior chamber paracentesis will reduce the amount of ischemic time and possible permanent visual impairment.

Multiple studies have repeatedly demonstrated the efficacy and safety of an anterior chamber paracentesis when used acutely to reduce IOP.^{11,12} It is a procedure routinely performed in the office setting but is often met with apprehension by the Emergency Physician. Emergency Physicians should become familiar with an anterior chamber paracentesis because it is safe, simple, effective, relatively quick, and has the potential to save a patient's vision.

Corneal Foreign Body Removal

Scott A. Heinrich and Dino P. Rumoro

INTRODUCTION

Corneal foreign bodies are a common complaint confronting Emergency Physicians and account for approximately 35% of all eye injuries seen.¹⁻³ Many objects have been implicated as a source of corneal foreign bodies (e.g., dirt, dust, glass, insects, metal, plant particles, and wood) (**Figure 191-1**).¹ Metal is the most frequently encountered ocular foreign body, often from hammering.⁴ Most ocular foreign bodies require prompt removal. More than 75% of retained foreign bodies presenting on the eye surface are corneal in nature and result in a keratitis if left in place for more than 3 days.⁵

The prevailing symptom that forces patients to seek treatment is the sensation of an ocular foreign body or the pain associated with the foreign body. A variety of techniques exist for removal of ocular foreign bodies. A discussion of each of these techniques is necessary to determine the proper technique for a given situation.

A

B

FIGURE 191-1. Corneal foreign bodies. **A.** The foreign body is just outside the visual axis with a surrounding rust ring. **B.** Metallic foreign body over the center of the visual axis.

ANATOMY AND PATHOPHYSIOLOGY

Many foreign bodies are diverted from the surface of the eye by the rapid blinking action of the eyelids and the eyelashes. A foreign body may not lodge itself into the cornea or the surrounding scleral surface if it is able to get past the eyelids and eyelashes. It may be washed to the inner canthus by a combination of blinking and tear flow. The foreign body may occasionally be carried away via drainage through the lacrimal ducts and into the nose.⁵ Objects may be found in the upper or lower fornices, the channels created by the fold of the inner surfaces of the eyelids in communication with the conjunctival surface of the eye. The foreign body in the upper fornix is typically found lodged in the subtarsal groove on the inner surface of the upper eyelid inferior to the tarsal plate.⁵ Foreign bodies may travel deeper into the respected fornices where they may be difficult to find. Foreign bodies may be lodged into the surface of the conjunctiva overlying the sclera or the cornea. Foreign bodies in the cornea carry the most risk of serious injury or permanent scarring.

The cornea is only millimeters thick. It is composed of five layers (from outer to inner layer): epithelium, Bowman's membrane, stroma, Descemet's membrane, and the endothelial layer that lies directly over the anterior chamber.⁶ The surface epithelium has five layers of squamous cells. Most superficial corneal foreign bodies become embedded in this layer and do not result in scarring. Bowman's membrane has no regenerative capacity, and if injured, scarring and permanent injury can result.⁷ **Foreign bodies that violate Bowman's membrane are considered deep corneal injuries.** The stroma is composed of collagen and accounts for the largest portion of the cornea. Descemet's membrane is a basement membrane that can be regenerated if injured. The final component of the cornea is the endothelial layer which is composed of a single row of cuboidal cells that can regenerate if damaged.

Healthy cells adjacent to the injury slide over the damaged site and eventually replicate to the previous number of cells present when the corneal epithelium is injured.⁴ The reepithelialization begins at the periphery and progresses toward the center of the corneal defect.⁸ Conjunctival epithelium migrates over the cornea to aid in its repair. This is true even if the entire surface corneal epithelium is removed.

Corneal innervation is provided by sensory nerve fibers located in the surface epithelium. These are concentrated primarily in the center of the cornea and sparsely located in the periphery.^{9,10} Injuries to the corneal epithelium produce foreign body sensations, pain, photophobia, and tearing.¹⁰ More pain occurs when the central portion of the cornea is affected due to the larger distribution of sensory nerves.¹⁰

Patients are good at identifying the location of an embedded foreign body due to the corneal innervation. A study evaluated 50 patients with corneal foreign bodies and their accuracy in identifying the foreign body location.¹¹ Eighteen patients (36%) were unable to identify the foreign body location, 14 (28%) identified the exact location, and 18 (36%) were partially correct in identifying the location based upon vertical and horizontal components. **Always acknowledge the patient's sensation of an ocular foreign body and evaluate the area thoroughly.**

The presence of a metallic foreign body in the cornea can result in a rust ring (Chapter 192) (**Figure 191-1**). This is identified as a brownish ring surrounding the foreign body. **The rust ring and the metallic foreign body must be removed from the cornea.** The rust ring may be removed at the time of the foreign body removal or within 24 hours by an Ophthalmologist.

INDICATIONS

All foreign bodies involving the eye must be removed. They do not all need to be removed immediately in the Emergency Department. Foreign bodies that are superficial and located on

A

B

FIGURE 191-2. A foreign body under the upper eyelid. **A.** Clinical photo. (Reprinted with permission from Dr. Karin Lecuona, University of Cape Town.) **B.** Multiple vertical lines/abrasions seen using fluorescein. (Used with permission from Sonoran Desert Eye Center.)

the cornea, eyelid, lower fornix, sclera, or upper fornix can safely be removed by the Emergency Physician. Metallic foreign bodies require prompt removal to avoid the formation of a rust ring. The rust ring can be removed by the Emergency Physician with the foreign body or by an Ophthalmologist at the 24-hour follow-up visit. Vertical abrasions on the cornea during the fluorescein examination are indicative of a foreign body under the eyelid. Evert the upper eyelid to evaluate for the presence of a foreign body and remove it if one is found (Figures 191-2).¹²

CONTRAINDICATIONS

Corneal foreign bodies located in the direct axis of vision can cause permanent visual disturbances if improperly removed (Figure 191-1B).^{2,7} Consult an Ophthalmologist before removing these foreign bodies as they often prefer to remove them. Deeply embedded objects or multiple foreign bodies that would require extensive debridement can result in significant scarring.¹ Consult an Ophthalmologist before attempting to remove these foreign bodies. **Avoid any manipulation of the eye if a perforated globe is suspected based upon either the direct examination of the eye or the mechanism of injury.** Foreign bodies embedded deeply within the cornea may be left in place if they are composed of an inert substance (e.g., glass).¹ This avoids the possibility of additional scarring from extensive debridement if the object is below the corneal surface and

allows for healing of the epithelium over the object. **The decision to leave a corneal foreign body must be made in conjunction with an Ophthalmologist.** Consult an Ophthalmologist if an infection is associated with the foreign body (e.g., corneal clouding, corneal edema, or a purulent discharge). Refer injuries to an Ophthalmologist when they are old, the foreign body has been covered by corneal epithelium, or the foreign body is resistant to removal. Do not attempt to extract a corneal foreign body if the patient is confused or uncooperative as this can result in a perforated globe. Consider the use of intravenous sedation, procedural sedation (Chapter 159), or general anesthesia to extract the foreign body after consulting an Ophthalmologist.

EQUIPMENT

- Slit lamp
- Cotton-tipped applicator
- Corneal spud
- Ringer's lactate solution or normal saline
- Intravenous (IV) tubing
- 25 or 27 gauge needle
- Tuberculin syringe with needle
- Topical ocular anesthetic solution (e.g., proparacaine or tetracaine)
- Topical ophthalmic antibiotic
- Cycloplegic agents (e.g., cyclopentolate, homatropine, or tropicamide)
- Fluorescein strips or liquid
- Electric burr drill and burrs
- Eye patches
- Adhesive tape
- Benzoin solution
- Wood's lamp, if slit lamp is not available
- Eidolon Bluminator, if slit lamp is not available

Having a slit lamp available is preferred when removing a corneal foreign body (Chapter 185). There are alternatives if a slit lamp is not available or the Emergency Physician does not feel comfortable with using a slit lamp. The Wood's lamp can provide the appropriate blue light required for fluorescein staining and rust ring removal (Figure 191-3A). This portable device has a built-in magnification lens. It has several disadvantages including having to be plugged into an outlet, an awkward shape, and a heaviness that must be balanced while using it. A device known as the Eidolon Bluminator (Eidolon Optical LLC, Natick, MA) is commercially available (Figure 191-3B). It is a small, hand-held, self-contained, battery-powered device and includes a 7× magnification lens.

PATIENT PREPARATION

Perform a complete eye examination prior to removing a foreign body (Chapter 185). Measure visual acuities prior to any ocular procedure and following the procedure to document any changes. Note any irregularities in the contour of the eye, any loss of anterior chamber depth, prolapse of the iris through a corneal laceration, focal injection, a hyphema, or lens opacification. These signs may indicate a ruptured globe that requires an emergent Ophthalmology consultation.⁷ Update the patient's tetanus immune status if needed.

Apply a topical ocular anesthetic agent into the affected eye if the patient has no allergies. Vary the beam of light from the slit lamp in its direction of illumination from direct exposure to indirect

A

B

FIGURE 191-3. Alternatives to the slit lamp. **A.** Wood's lamp. **B.** Eidolon Bluminator.

exposure and tangential exposure to highlight any surface defects.¹³ Examine the anterior chamber for cells and flare that occur in older injuries as a result from a secondary iritis. The patient typically suffers from the discomfort of an anterior uveitis rather than the foreign body.¹

Stain the eye with fluorescein dye (**Figure 185-26**). Fluorescein can permanently stain contact lenses and should not be used in their presence. Remove the contact lens before fluorescein staining (Chapter 186). Illuminate the eye with a cobalt blue light. Look for the green reflection of a corneal abrasion. Observe the site for the flow of fluorescein stain away from the site of a corneal puncture as anterior chamber fluid flows forward (i.e., Seidel sign, **Figure 185-28**).^{7,13} **A positive Seidel sign indicates a ruptured globe.** Multiple vertical abrasions on the cornea during the fluorescein examination are indicative of a foreign body under the eyelid (**Figure 191-2B**). Irrigate the fluorescein stain from the eye after the examination is complete to avoid any chemical-induced irritation.

Explain the risks, benefits, and alternative procedures to the patient and/or their representative for the corneal foreign body

removal. Obtain an informed consent for the procedure and place this in the medical record. When performing the procedure on a neonate or child, it is advisable to give the parent the option to leave the room or look away as the procedure can be disconcerting to some parents. Instill additional topical ophthalmic anesthetic solution as necessary.

TECHNIQUES

EYELID FOREIGN BODIES

Evert the upper eyelid (Chapter 185).¹³ Instruct the patient to look downward. Use a cotton-tipped applicator to gently press on the upper eyelid over the tarsal plate. Grasp the eyelashes with a thumb and index finger. Pull the upper eyelid outward, downward, and upward to evert it over the applicator (**Figure 185-17**). Examine the undersurface of the eyelid for foreign bodies (**Figure 191-2**). Remove any foreign bodies by sweeping the area with a saline moistened cotton-tipped applicator (**Figure 191-4**).

Double evert the eyelid. Lift the inferior edge of the eyelid created by the initial eversion. This is accomplished by using a cotton-tipped applicator or an appropriate eyelid retractor (**Figures 185-19 and 185-20**). Examine the sclera and conjunctiva for a foreign body. Release the eyelid and instruct the patient to blink their eyes. This allows the upper eyelid to return to normal.

Evert the lower eyelid by pulling the lower eyelashes forward while the patient looks upward (**Figure 185-18**).⁷ Examine the area. Sweep the scleral and palpebral (i.e., eyelid) conjunctival area with a saline-soaked cotton-tipped applicator if the patient experiences a foreign body sensation but no debris can be visualized.

IRRIGATION

Superficial foreign bodies on the conjunctiva or the cornea can sometimes be removed by using an irrigation technique (Chapter 187). A brief description is presented in this section. **Never use Morgan or Mediflow lenses (Figure 187-5) for eye irrigation in the face of a foreign body as it may lodge the object further into the cornea.**

The most appropriate solution to use is Ringer's lactate solution followed by normal saline. Tap water can be used in the prehospital setting. Ringer's lactate solution causes less irritation. The pH range of lactated Ringer's is 6.0 to 7.2 and is closer to the normal pH (i.e., 7.4) of the eye in comparison to the pH of 4.5 to 6.0 of normal saline.⁷

Place the patient supine with their head tilted toward the side being irrigated to aid in proper runoff of the irrigant. Hang the IV fluid bag above the patient's head. Insert the IV tubing spike into

FIGURE 191-4. Evert the eyelids and remove the foreign body with a moistened cotton-tipped applicator.

the port on the IV fluid bag. Flush the patient's eye with sterile IV solution through the open end of the IV tubing while holding the patient's eyelids open (**Figure 187-3**). Flush from the scleral surface with the flow of solution directed over the cornea, thus washing the object out of the eye.^{1,7,13} **Never direct the solution onto the object to avoid embedding it deeper into the soft underlying tissues. Never direct the flow directly onto the surface of the cornea to avoid secondary injury.** Use a forceps or cotton-tipped applicator to remove objects flushed onto the palpebral conjunctiva.⁷ **Never use forceps on the eye.**

COTTON-TIPPED APPLICATOR

Use a cotton-tipped applicator premoistened with saline to remove a foreign body from the conjunctiva overlying the sclera or the eyelids (**Figure 191-4**).¹³ Gently touch the premoistened tip of the cotton-tipped applicator to the conjunctival surface and lift off the foreign body. **Do not use the cotton-tipped applicator to remove a foreign body from the cornea.**¹³ It can result in a large corneal abrasion by removing the surface epithelium.

MANUAL EXTRACTION

Extract the foreign body with a corneal spud or hypodermic needle if it is not removed via irrigation or if it is embedded superficially into the corneal surface.^{14,15} A corneal spud is made of stainless steel that comes in a variety of shapes (**Figure 192-3**). It generally consists of a sharpened metal tip attached to a handle.¹ It is used to lift off or to carve out a corneal foreign body.¹ Many prefer to use a tuberculin syringe with a bent or straight needle. It allows better control of the needle by using the syringe portion as the grip. The authors always use a saline-filled tuberculin syringe. This allows the Emergency Physician to apply saline drops to moisten the eye as well as to flush away the foreign body after it is dislodged. An 18 gauge needle has been described for the removal of large foreign bodies because of its wide diameter.¹ The instrument used is physician dependent. **Proper explanation of the extraction procedure**

using a needle will often ease a nervous patient and ensure better compliance by limiting unexpected movements.

Perform the procedure under direct visualization with the slit lamp. Place the patient seated at the slit lamp with their head firmly in place against the forehead rest to avoid any unexpected movement (**Figure 191-5A**). The foreign body can be removed using the blue light of a Wood's lamp or Eidolon Bluminator if a slit lamp is not available. Hold the needle, or spud, between the thumb and index finger of the dominant hand as one would a pencil. Have the bevel facing the examiner. Stabilize the dominant hand on the patient or the slit lamp apparatus using the remaining fingers. Instruct the patient to focus their vision on a given point to avoid any eye movement.

Approximate the tip of the needle, or spud, to the foreign body with the naked eye before utilizing the slit lamp microscope to avoid inadvertent injury. Approach the foreign body from the periphery and not across the patient's field of vision (Figure 191-5B). Gently tease out the foreign body using the beveled edge of the needle, or spud, in a tangential direction in relation to the eye to avoid inadvertent deep puncture if the patient suddenly moves (**Figures 191-5C and 191-6**).¹⁶ Use the tip to gently pry the foreign body loose if necessary but extreme care must be exercised (**Figure 191-5D**). Remove the loose foreign body with a moistened cotton-tipped applicator or with gentle irrigation.

ELECTRIC BURR DRILL EXTRACTION

An electric battery-powered drill equipped with various sized diamond dental burrs can be used for foreign body removal (**Figure 191-7**). Its use is typically associated with an increased tissue defect when compared to using a needle or a spud.¹⁷ **Use caution as the burr drill can embed the foreign body deeper into the cornea.**

Choose a burr size that is slightly larger than the diameter of the foreign body. Load the burr onto the drill (**Figure 191-7**). Grasp the device like a pencil using the thumb and middle finger. Press the finger bar on the drill with the index finger to turn on the drill and

FIGURE 191-8. Removal of a corneal foreign body with a burr drill.

rotate the burr bit. Approach the foreign body tangentially to the eye (**Figure 191-8**). Gently place the rotating burr bit on the area to be debrided using short applications of one to two rotations of the burr. Lift the burr from the cornea after each application to examine the area and determine if the foreign body has been removed.

ASSESSMENT

Carefully examine the cornea under the slit lamp with and without the use of fluorescein dye. Ensure that the foreign body is completely removed. Consult an Ophthalmologist if the foreign body has broken off, is deeply embedded within the cornea, or is associated with a rust ring. Measure and record the patient's visual acuity after the extraction procedure. Compare this to the preextraction visual acuity. Consult an Ophthalmologist if there is a difference in the preextraction and postextraction visual acuity.

AFTERCARE

A corneal abrasion will be present upon removal of the foreign body. The defect is usually larger than the original foreign body and should be treated as a typical corneal abrasion. The average time to resolution of the epithelial defect is approximately 4.3 days.⁸ Place a broad-spectrum ophthalmic antibiotic ointment or drops (e.g., a fluoroquinolone) on the eye.¹⁸ Instruct the patient to instill topical broad-spectrum antibiotics every 4 hours if the eye is not patched.^{1,7,9,13} Ophthalmic nonsteroidal anti-inflammatory drugs (NSAIDs) are safe to use and provide effective pain relief, especially in patients who can afford the medication and must return to work immediately.¹⁹⁻²²

The use of an eye patch is controversial and usually not required (Chapter 193). A review showed that patching simple corneal abrasions may not improve healing or pain.²³ Consider the use of eye patches cautiously as they may be associated with additional discomfort, delayed healing, and the conversion of a corneal abrasion into a corneal ulcer.²⁴ Consider patching the eye closed if the defect is large and painful. Avoid pressure patching the eye in the case of small, superficial, or minimally painful abrasions. Avoid the use of eye patches in organic foreign bodies and patients who wear contact lenses as the bacterial milieu is favorable for the development of a local infection.⁷ Consult an Ophthalmologist before patching an eye.

The proper method of applying an eye patch is to first administer all necessary medications. Instruct the patient to close both eyes. Apply a folded patch to the affected eye with the rounded edge pointed downward. Place an unfolded patch over the folded patch. Prep the skin with a benzoin solution to aid with tape adherence.

Apply strips of tape from the medial aspect of the forehead, over the patch, and to the lateral cheek (**Figure 193-2**). Apply the tape tightly enough to prevent eye opening but lightly enough to not cause discomfort. Apply strips of tape repeatedly over the patch until it is entirely covered. Apply the final pieces of tape over the center of the patch while holding the cheek soft tissue superiorly. This will ensure that the cheek, when released, will pull the bandage taut and avoid loosening.^{7,13}

Cycloplegics (e.g., 1% cyclopentolate) can be used to alleviate pain or to limit pain with significant corneal defects or an anterior uveitis.¹ Topical steroids have no place in the treatment of traumatic corneal defects.¹ Oral analgesics are appropriate in cases of persistent discomfort but may not help. **Historically, topical ocular anesthetic agents were not prescribed due to their abusive potential and the direct deleterious effects of the anesthetic on the corneal epithelium.**⁷ This toxicity was noted in animal studies with prolonged exposure or case reports of patient abuse.²⁵⁻²⁷ Limited data suggest that dilute topical anesthetics for a short course may be effective.²⁸⁻³³ Their safety for outpatient use is to be decided by each Emergency Physician.

Refer all patients to an Ophthalmologist for reexamination in 24 hours, especially if an eye patch has been applied. A rust ring can be removed by the Ophthalmologist at the follow-up visit. Instruct the patient not to operate a vehicle if the eye is patched. These instructions hold true if the eye is not patched but a procedure was performed to remove a foreign body.

Many eye injuries occur while at work due to failure to comply with wearing eye protection, resulting in a significant loss of working hours.^{10,11,34-37} Take the time necessary to explain the importance of wearing safety goggles if the injury occurred while at work, gardening, or participating in hobbies (e.g., woodworking, drilling, auto repair).

COMPLICATIONS

A foreign body will occasionally not be able to be removed in the Emergency Department. Refer the patient to an Ophthalmologist for definitive treatment before further attempts at removal result in severe ocular injury and the potential for violation of the anterior chamber (i.e., perforation of the globe). **Notify an Ophthalmologist immediately if inadvertent puncture of the globe occurs from attempts at foreign body removal because a surgical emergency now exists.**

Improper placement of eye patches can cause a corneal ulcer or delayed corneal healing.¹³ Caution the patient against driving while the eye is patched due to impaired depth perception.¹³

Continued discomfort at the 24-hour follow-up may indicate an anterior uveitis is present, a corneal rust ring from a metallic object has formed, the foreign body was not completely removed, or an infection or penetrating eye injury is present.¹ Contaminated corneal foreign bodies or those consisting of vegetative material can lead to corneal ulceration from the introduction of bacteria.¹

Corneal defects will not always be completely healed at the 24-hour follow-up. The eye may require 1 additional day of patching if the defect is still a significant size. Treat the defect by applying a topical antibiotic for several more days if the defect is markedly smaller than the original injury.¹

Care must be taken to avoid further damage to the eye when treating children or patients who are uncooperative. IV sedation and analgesia (Chapter 159) can be used in these situations. Consult an Ophthalmologist for treatment under general anesthesia if sedation is contraindicated or if not comfortable with removing the foreign body under procedural sedation.⁷

SUMMARY

Corneal foreign bodies are routinely encountered in the Emergency Department. They must be definitively treated to avoid long-lasting ocular disability. Documentation of a complete history and physical examination of the eye is mandatory before attempting to remove a foreign body. The most reliable method of corneal foreign body removal is the use of a hypodermic needle or corneal spud, taking care to avoid additional ocular trauma. Administer appropriate antibiotics and/or cycloplegics after removal of the foreign body. The application of an eye patch is not required after the foreign body is removed in most cases. The decision to apply an eye patch is best done in consultation with an Ophthalmologist. Refer the patient to an Ophthalmologist in 24 hours for evaluation of proper healing and the immediate treatment of any evolving complications.

Corneal Rust Ring Removal

Adam Jennings, Marcus Holmes, and Devin Sandlin

INTRODUCTION

Corneal rust rings occur commonly when metallic foreign bodies become embedded in the cornea (**Figure 192-1**). **Removal of the rust ring is imperative to avoid permanent staining of the cornea, persistent inflammation, or disruption of corneal integrity (i.e., necrosis) with loss of stromal substance.**¹⁻³ Two techniques for the removal of rust rings are discussed. Topical deferoxamine as

FIGURE 192-1. The corneal rust ring. (Used with permission from Tintinalli JE, et al: *Tintinalli's Emergency Medicine: A Comprehensive Study Guide*, 8th ed. New York: McGraw-Hill; 2016.)

a chemical chelator should only be used by an Ophthalmologist and is mentioned only for the sake of completeness.

ANATOMY AND PATHOPHYSIOLOGY

The cornea is approximately 0.5 mm thick and is composed of five layers. From the outer to inner layer is the corneal epithelium, Bowman's membrane, stroma (largest layer), Descemet's membrane, an endothelial layer, lies directly over the anterior chamber. **Corneal rust rings are formed from the oxidation of iron present in metallic foreign bodies.**⁴ As little as 3 hours of corneal contact are required to form the brown stain of a rust ring.¹

INDICATIONS

All corneal metallic foreign bodies require prompt removal to avoid the possibility of rust ring formation. A rust ring requires complete removal in a timely fashion in order to avoid the damaging effects of rust on the cornea. While foreign bodies should be removed in the Emergency Department, the rust ring can be left for the Ophthalmologist to remove within 24 to 48 hours if the Emergency Physician does not feel comfortable removing the rust ring.

CONTRAINDICATIONS

Corneal foreign bodies and rust rings that are located in the direct axis of vision can cause permanent visual disturbances if improperly removed.² Consult an Ophthalmologist before removing these as they often prefer to remove them. Do not attempt to extract a rust ring if the patient is a young child, confused, or uncooperative as this can result in a perforated globe. These patients may require the use of intravenous sedation, procedural sedation (Chapter 159), or general anesthesia to extract the rust ring.

EQUIPMENT

- Slit lamp
- 25 or 27 gauge needle
- Tuberculin syringe with a needle
- Burr drill
- Burr bits
- Topical ocular anesthetic agent (e.g., proparacaine or tetracaine)
- Topical ophthalmic antibiotic
- Cycloplegic agents (e.g., cyclopentolate, homatropine, or tropicamide)
- Ringer's lactate solution or normal saline
- Fluorescein strips or liquid
- Wood's lamp, if a slit lamp is not available
- Eidolon Bluminator, if a slit lamp is not available
- Ophthalmic foreign body instruments, optional⁵

Having the availability of a slit lamp is preferred when removing a corneal rust ring.⁶ There are alternatives if a slit lamp is not available or the Emergency Physician does not feel comfortable with using a slit lamp (**Figure 191-3**). The Wood's lamp can provide the appropriate blue light required for fluorescein staining and rust ring removal. This portable device has a built-in magnification lens. It has several disadvantages including having to be plugged into an outlet, an awkward shape, and a heaviness that must be balanced while using it. A newer device is the Eidolon Bluminator (Eidolon Optical LLC, Natick, MA). It is a small, hand-held, self-contained, battery-powered device and includes a 7× magnification lens.

FIGURE 192-2. Positioning of the patient and the emergency physician's hand.

PATIENT PREPARATION

Explain the procedure, its risks, and benefits to the patient and/or their representative. A calm and thorough explanation of what is going to occur and showing the tools to be used provides an adequate anxiolytic effect. Obtain a signed informed consent to perform this procedure. Apply a topical ocular anesthetic agent into the affected eye.^{7,8} Determine the patient's visual acuity in the affected eye. Seat the patient at the slit lamp with their head firmly in place to avoid any unexpected movement (**Figure 192-2**). **Examine the eye via the slit lamp and rule out the possibility of an intraocular foreign body with a corneal perforation.** Perform a complete eye examination to rule out any other ocular problems. Remove the corneal foreign body (Chapter 191) if it is still present with the hypodermic needle, tuberculin syringe, or ophthalmologic instrument. The rust ring will often be removed simultaneously with the metallic foreign body. Make an attempt to remove the rust ring if it remains after removal of the foreign body.

TECHNIQUES

MANUAL EXTRACTION

Scrape out the rust ring in a similar fashion to the removal of a metallic foreign body (Chapter 191). **The entire area of rust-stained epithelium must be completely removed without any residual rust.**

Extract the rust ring with a corneal spud, another ophthalmologic instrument, or a hypodermic needle (**Figure 192-3**). A corneal spud is a stainless steel device that comes in a variety of shapes. It generally consists of a sharpened metal tip attached to a handle.¹ It is used to lift off or to carve out a corneal foreign body or rust ring.¹ Many Emergency Physicians prefer to use a tuberculin syringe. It allows for better control of the needle by using the syringe portion as the grip. The author always uses a saline-filled tuberculin syringe. Others use a needle that they bend attached to a syringe.⁹ This allows the application of saline drops to moisten the eye as well as to flush away the rust ring after it is dislodged from the cornea. The instrument used is physician dependent. **Proper explanation of the extraction procedure using a needle will often ease a nervous patient and ensure better compliance by limiting unexpected movements.**

FIGURE 192-3. Instruments to manually remove a corneal rust ring. **A.** Corneal spud. **B.** Corneal dissector. **C.** Corneal foreign body needle.

Perform the procedure under direct visualization with the slit lamp. Place the patient seated at the slit lamp with their head firmly placed against the forehead rest to avoid any unexpected movement (**Figure 192-2**). The foreign body can be removed using the blue light of a Wood's lamp or Eidolon Bluminator if a slit lamp is not available. Hold the needle, or ophthalmologic instrument, between the thumb and index finger of the dominant hand with the bevel facing the examiner as one would hold a pencil. Stabilize the dominant hand on the patient or the slit lamp apparatus using the remaining fingers. Instruct the patient to focus their vision on a given point to avoid any eye movement.

Approximate the tip of the needle, or ophthalmologic instrument, to the rust ring with the naked eye before utilizing the slit lamp microscope in order to avoid inadvertent injury. Approach the rust ring from the periphery and not across the patient's field of vision (Figure 192-4A**). Gently tease out the rust ring using the beveled edge of the needle, or ophthalmologic instrument, in a tangential direction in relation to the eye to avoid inadvertent deep puncture if the patient suddenly moves. Use the tip to gently pry the rust ring loose if absolutely necessary (**Figure 192-4B**).**

FIGURE 192-4. Manual extraction of the rust ring.

FIGURE 192-5. An example of a corneal burr drill with a drill bit.

Extreme care must be exercised. Remove the loose rust ring with a moistened cotton-tipped applicator or with gentle irrigation.

ELECTRIC BURR DRILL EXTRACTION

An electric battery-powered burr drill equipped with diamond burrs can be used for rust ring removal (Figures 192-5 and 192-6).¹⁰ The burr bit cuts away corneal tissue very slowly. Corneal rust rings were induced in rabbits and comparisons were made between manual extraction versus electric burr drill extraction.¹ Both were equally effective for rust ring removal but the burr drill caused a deeper corneal defect. **Use caution when using an electric burr drill.** There was no difference in corneal scarring between the two techniques. The burr drill can also be used to extract rust located in the bulbar conjunctiva.¹¹

Choose a burr size that is slightly larger than the diameter of the rust ring. Load the burr onto the drill. Grasp the device like a pencil using the thumb and middle finger. Press the finger bar on the drill with the index finger to turn on the drill and rotate the burr bit. Other burr drills turn on with a screw-type mechanism on the burr drill (Figure 192-5). Approach the rust ring tangentially to the eye (Figure 192-6A). Gently place the rotating burr bit on the area to be debrided using short applications of one to two rotations of the burr (Figure 192-6B). Lift the burr from the cornea after each application to examine the area and determine if the rust ring has been removed. **Thoroughly inspect the base of the crater to ensure that it is free of rust.**¹¹ Continue the process until the rust ring is removed. Use a slightly larger burr bit if rust still remains along the periphery of the crater.

FIGURE 192-6. Burr drill extraction of the rust ring.

DELAYED REMOVAL

The rust ring may be removed after it ages.^{2,5,12} Allow the rust ring to remain for 24 to 48 hours. During this time, the iron deposits will kill the surrounding corneal epithelial cells. The rust ring will “soften” and be easily removed in one piece with a needle, ophthalmologic instrument, or burr drill. **Do not allow the rust ring to remain for longer than 24 to 48 hours as it can cause significant damage to the cornea.**

CHEMICAL CHELATION

Topical deferoxamine has been used experimentally for the nonsurgical removal of rust stains on the cornea.¹³ It has been shown to remove rust, although perhaps not as reliably as the methods previously described. The potential exists for resultant eye irritation, corneal ulceration, or persistence of the rust stain.¹³ The clinical use of deferoxamine should be done only in very select situations such as in children with multiple lesions or when the central axis of vision is involved.¹⁴ This technique is reserved for the Ophthalmologist and is therefore not described in this text.

ASSESSMENT

Measure and document visual acuities before and after the procedure. Consult an Ophthalmologist if the postprocedural visual acuity is different from the preprocedural visual acuity.

AFTERCARE

A corneal defect resembling a corneal abrasion will be present after the rust ring is removed. The defect is usually larger than the original foreign body and should be treated as a typical corneal abrasion. Apply topical ocular antibiotic ointment in the eye. The use of an eye patch (Chapter 193) is controversial but considered by most as unnecessary. Contact lens wearers should switch to glasses until the eye is fully healed and evaluated by the Ophthalmologist. Instruct the patient not to operate a vehicle if possible. Administer cycloplegics to alleviate pain from an actual or potential anterior uveitis.² Oral analgesics are appropriate in cases of persistent discomfort. Consider prescribing topical nonsteroidal anti-inflammatory drugs (NSAIDs) for pain relief (e.g., bromfenac, diclofenac, or ketorolac).¹⁵ Refer the patient to an Ophthalmologist for reexamination in 24 hours. The patient requires daily follow-up and corneal staining to ensure proper healing.¹⁶

Instruct the patient on the importance of proper eye protection.¹⁷ Many eye injuries occur while at work due to failure to comply with wearing eye protection and result in a significant loss of working hours.^{7,18,19} Take the time that is necessary to explain the importance of wearing safety goggles if the injury occurred while at work, gardening, or participating in hobbies (e.g., woodworking, drilling, and auto repair). The prevention of ocular foreign bodies and rust rings is preferable to treating them.²⁰

Some consider sending the patient home with topical anesthetic eye drops.^{7,21-24} Diluted drops are used for outpatients for the

management of pain from a photorefractive keratotomy and other ophthalmic procedures. The use of these topical medications as an outpatient from the Emergency Department is controversial. This decision is left up to each Emergency Physician, their department protocols, and in consultation with local Ophthalmologists.

COMPLICATIONS

Abandon multiple attempts at removal of the rust ring to avoid severe ocular injury and the potential for violation of the anterior chamber if the depth of the rust cannot be determined or if repeated debridement is unable to completely remove the rust ring. The eye can be left unpatched for 24 hours and the patient referred to an Ophthalmologist for definitive removal the following day in these situations or in cases of hesitancy in removing a rust ring. Delayed removal is often easier than the initial attempts due to further oxidation and injury of the corneal epithelium resulting in “softening” of the rust. The “softened” rust ring is easily scraped out in 24 to 48 hours.² The rust ring can lead to chronic inflammation, corneal necrosis, corneal vascularization, or permanent scarring.³

SUMMARY

Removal of corneal rust rings is imperative in order to avoid permanent ocular injury. It is best accomplished with a small-gauge hypodermic needle or with an electric burr device. An alternative approach is to leave the rust ring for delayed removal by an Ophthalmologist in 24 hours when the rust has “softened.” It is essential to completely remove the rust ring to prevent future ocular morbidity. The procedure is simple to perform with readily available equipment.

Eye Patching and Eye Shields

Teresa D. Le and Adam R. Jennings

INTRODUCTION

Eye shields are used to protect the eye from further injury when the integrity of the globe is compromised or potentially compromised.¹ The best results are obtained when early repair of globe disruption occurs and before any globe contents leak out or change position.^{2,3} Eye patches are intended to prevent movement of the eyelid over an injured but intact cornea.^{1,4,5} Eye patching has historically been used to protect the eye from bright light, to facilitate healing of a corneal abrasion, or to protect the cornea from injury during sleep. There have been no substantial changes in the indications for eye shields and their method of application.⁶⁻⁹ Eye patching has become increasingly controversial.⁶⁻¹⁰

EYE SHIELDS

INDICATIONS

Eye shields serve as temporary protection for patients in whom a penetrated or ruptured globe is suspected.¹¹⁻¹³ The purpose is to prevent further injury as extravasation of globe contents is associated with poor vision outcomes.^{3,14} **A ruptured globe is a vision-threatening emergency.** The signs associated with a ruptured globe include bloody chemosis, increase or decrease in the depth of the anterior chamber, irregular or peaked iris, positive Seidel test, vitreous hemorrhage, low intraocular pressure, hyphema, and loss of visual acuity.^{12,13,15-17} Globe rupture should also be suspected from penetrating corneal wounds from foreign bodies (e.g., tiny pieces of metal).^{18,19} **Further eye examination or eye manipulation is contraindicated if a ruptured globe is suspected. Do not measure intraocular pressure. It can worsen or cause the extrusion of globe contents.**²⁰ An eye shield is applied immediately and to remain in place while other injuries are managed, tests are obtained (e.g., orbital computed tomography [CT] scans), and the consulting Ophthalmologist is contacted.^{3,13}

CONTRAINDICATIONS

The only contraindication to the application of an eye shield arises when the surrounding face and orbits are so extensively damaged that the metal shield or its edges will directly injure the globe. The

FIGURE 193-1. A paper cup may be used if a commercial eye shield is not available. The top of the cup is cut in multiple places, and the resulting “flaps” are bent down to create a flat surface.

protective function of the eye shield relies on its edges being supported by the orbital rim, frontal bone, and maxillary bone.

EQUIPMENT

- Metal or plastic eye shield
- 1 inch tape

Most Emergency Departments stock commercially available eye shields. A clean, disposable paper drinking cup may be used if an eye shield is not available.^{5,21} Use a scissors to make 3/4 to 1 inch deep cuts around the open end of the cup (**Figure 193-1**). Make approximately six to eight cuts around the circumference of the cup. Fold the flaps on the open end of the cup outward. **Styrofoam cups are not suitable because the flaps can easily break off and cause further injury to the globe.**

PATIENT PREPARATION

The first procedure in patients with a suspected globe disruption is the application of the eye shield.^{13,16} There should be no preparations except to dry the area of skin that will receive the securing tape. Do not irrigate the eye, place any gauze or patch touching the eye, and/or apply ocular ointments or drops. Ocular tonometry is also contraindicated.¹³ All the previously mentioned

interventions are likely to cause further injury to the exposed globe.^{3,22} Contact an Ophthalmologist immediately to expedite globe repair.^{12,13,16} Obtain a CT scan of the orbits if a foreign body may have possibly penetrated the globe.^{19,23}

It may be possible in the future to determine if a globe is ruptured without the radiation associated with a CT scan. A portable sensor is being developed that is inexpensive and can quickly determine if the globe has been penetrated.²⁴ The device measures vitamin C levels in the eye fluid. The interior of the globe has much higher levels than the normal tear film. Penetrating injury results in the aqueous fluid leaking out and causes the tear fluid to have a higher level of vitamin C.

TECHNIQUE

Apply the commercial eye shield (**Figure 193-2A**) or the one improvised from a paper cup (**Figure 193-2B**) over the injured eye. **Ensure that its edges do not contact structures any closer to the eye than the orbital rim.** Tear off four to six strips of 1 inch tape, each 4 to 5 inches long. Apply the strips of tape diagonally from the center of the forehead to the cheek above the mandible to hold the shield in place (**Figures 193-2A and 193-2B**).²¹

Care must be taken to avoid taping the nasolabial folds, lips, facial hair, and skin over the mandible.^{4,5} Otherwise the mandibular movement of eating and talking may cause the eye shield to move and potentially injure the eye. The tape may not stick if the patient has facial hair. The patient may benefit from a quick shave in the Emergency Department. Some patients require the use of an oxygen mask. Trim the oxygen mask around the eye shield to prevent it from displacing the eye shield and causing further eye injury.

ALTERNATIVE TECHNIQUE

An alternative to the eye shield is a moisture chamber (Good-Lite Co., Elgin, IL). These foam-edge devices have a clear lens (**Figure 193-3**). These devices are not latex, fit over the eye, prevent air flow into the eye, and are comfortable to wear. They also avoid any issues related to taping. Apply the moisture chamber followed by gauze to prevent the patient from seeing and accommodating with the injured eye.

FIGURE 193-2. Eye shields. **A.** A commercial eye shield is applied. **B.** An improvised eye shield is applied.

FIGURE 193-3. Moisture chambers. **A.** Single moisture chamber. **B.** Moisture chamber goggles. (Photos courtesy of Good-Lite Company.)

AFTERCARE

The eye shield position should frequently be checked for any movement or loosening of the tape due to blood, perspiration, or other fluids. **The shield must remain in place until tests demonstrate that the globe is intact or the consulting Ophthalmologist arrives.** Do not allow the patient to eat or drink. Additional therapy includes tetanus prophylaxis, prophylactic intravenous antibiotics, and parenteral antiemetics for nausea.^{2,3,13,16,17,22} Vomiting will cause extrusion of the contents of the globe.^{2,3,13,16,17,22} Position the patient with their head elevated if not contraindicated.

COMPLICATIONS

Poor positioning or shield movement can further injure the eye or cause extravasation of the globe contents. **The patient must be handled gently.** Wincing or squinting of the eye can increase intraocular pressure sufficiently to cause the extravasation of the contents of the globe.

EYE PATCHING

INDICATIONS

The indications for eye patches are steadily being reduced as a growing body of literature shows no benefit and potential harm.¹⁰ Patches were indicated for corneal injuries due to abrasions, thermal burns, light burns, or chemical burns.⁴ Patches were believed to promote healing and provide pain relief by decreasing movement of the eyelid across the recovering cornea.^{4,5} Patches also block light in photophobic patients with ciliary spasm or reactive iritis due to corneal injuries.

Most of these assumptions are now questioned. Patching is believed to decrease corneal oxygenation, increase eye temperature, and increase corneal infection risk.^{14,25,26} Patches can cause injury if the eye opens underneath it. Numerous trials and meta-analyses comparing patients with corneal abrasions receiving patching versus no patching have found no difference in pain scores or healing time for small abrasions less than 10 mm in diameter.^{6-9,27} Decreased

healing time was observed for patched patients with abrasions greater than 10 mm in diameter.^{25,26} Patching is still recommended for patients with large defects but most authors also recommend further study in this group.⁸

Soft contact lens bandages have been used for patients who must maintain binocular vision.^{28,29} Eye patches were also previously indicated during sleep to protect the cornea in patients with facial nerve palsy (e.g., Bell's palsy) and the inability to completely close their eyes.³⁰ Current recommendations include applying ophthalmologic lubricants with or without an eye shield in this group.³¹

CONTRAINDICATIONS

Absolute contraindications to eye patching are corneal abrasions due to the wearing of contact lenses. There is an increased incidence of infection and more pathogenic bacteria harbored by contact lens wearers.²⁵ **Do not place an eye patch on any patient considered at risk for penetration or rupture of their globe.**¹³ Eye patching will increase intraocular pressure and may cause extravasation of the contents of the globe.¹⁹ Patients must be carefully assessed for the presence of corneal ulcers masquerading as abrasions.⁴ Eye patching of a corneal ulcer may place pressure on the friable tissue causing a deepening of the ulcer, subsequent globe perforation, and promotion of infection.

Relative contraindications are related to abrasion size and individual patient needs. Small abrasions heal well without patching. Patients who require binocular vision to function will benefit from not patching.^{8,25,26} Patches that come loose and allow eyelid movement are more painful for patients than no patch. Contraindications to ophthalmoplegics used in conjunction with patches are patients with known glaucoma or narrow angles on physical examination.⁴ The contraindication to contact lens bandages is an abrasion in a patient who was wearing contact lenses because of the risk of infection.¹²

EQUIPMENT

- Cycloplegic drops to reduce photophobia (e.g., 1% cyclopentolate or 5% homatropine)^{5,14,25}
- Broad-spectrum antibiotic ointment or drops
- Cotton eye patches
- 1 inch tape
- Contact bandage soft lens with a power of minus 0.5 diopters²⁹

PATIENT PREPARATION

Conduct a complete eye examination (Chapter 185) to ensure the integrity of the globe, the absence of an infection, and the absence of a foreign body. Document the visual acuity for both eyes.²¹ Patients should receive tetanus prophylaxis if their immunizations are not up to date.⁵ Apply cycloplegic drops and antibiotic ointment to the affected eye.^{4,5} Obtain a CT scan of the orbits if a foreign body may have possibly penetrated the globe.^{19,23}

TECHNIQUE

Instruct the patient to close both eyes and to keep them both shut for the remainder of the procedure. Tear off four to six strips of 1 inch tape, each 4 to 5 inches long. Obtain two cotton eye patches. Fold the first patch in half. Apply it to the affected eye while both eyes remain closed. Place the second unfolded patch over the first patch (**Figure 193-4A**). Apply the pretorn strips of tape diagonally from the center of the forehead to the cheek just above the mandible (**Figure 193-4B**).^{4,5} Lift the lower cheek up slightly before securing

FIGURE 193-4. Eye patching. **A.** A folded patch is applied over the eyelid then covered by an unfolded patch. **B.** The patch is secured with tape.

the first two strips of tape to ensure the correct amount of pressure.^{4,5} The patch will hold the eye more securely if the nasal and temporal strips are placed in a slight arc concave toward the center of the eye.

Care must be taken to avoid taping the nasolabial folds, lips, facial hair, and the skin near the mandible.^{4,5} Otherwise the mandibular movement of eating and speaking may cause the eye shield to move and potentially injure the eye. The tape may not stick if the patient has facial hair. The patient may benefit from a quick shave in the Emergency Department. Some patients require the use of an oxygen mask. Trim the oxygen mask around the eye patch to prevent it from displacing the eye patch and cause further eye injury.

SOFT CONTACT BANDAGE TECHNIQUE

Soft contact lenses can be applied as a corneal bandage for patients who require immediate use of both eyes.^{28,29} Prepare the patient as described previously. **Apply ophthalmic antibiotic drops rather than ointment to the affected eye.** Remove the contact lens from the storage bottle. Rinse the storage solution from the contact lens. Place the contact lens on the index finger of the dominant hand. Use the nondominant hand to open the patient's eyelids. Instruct the patient to look straight ahead. Gently apply the contact lens directly to the cornea. The patient should remain in the Emergency Department for a recheck in 15 to 30 minutes to make sure that the contact lens fits properly and they can tolerate it.²⁹

ALTERNATIVE TECHNIQUE

An alternative to the eye shield is a moisture chamber (Good-Lite Co., Elgin, IL). These foam-edge devices have a clear lens to allow the wearer to see through (**Figure 193-3**). These are not latex, fit over the eye, prevent air flow into the eye, and are comfortable to wear. They also avoid any issues related to taping. The plastic lens is scratch resistant.

ASSESSMENT

Refer to Chapter 185 on the examination of the eye for the complete details regarding the instillation of drops and ointment into the eyes. No further treatment is required for patients with small corneal abrasions. Make sure that the patient with an eye patch does

not feel the lid of the injured eye moving when they blink the unaffected eye.⁵ Ensure that the tape does not interfere with the patient's speech, chewing movements, or smiling.

AFTERCARE

Instruct the patient to remove the patch if it becomes loose. Eye patches should be changed or removed after 24 hours to reduce the risk of infection.^{4,5} Most patients will need oral pain medications for the first 24 hours in addition to the patch.⁵ Topical nonsteroidal anti-inflammatory ophthalmic drops have been useful alone or in conjunction with a contact lens bandage for pain relief.^{14,29,32-34} The patient must be reexamined in 24 hours by an Ophthalmologist for assessment of the healing progress, to check for infection, and to check for other complications. The patient can expect complete resolution in 2 to 3 days. Instruct the patient not to climb, drive, or operate dangerous equipment due to the loss of binocular depth perception.^{4,26} The elderly may need assistance with walking and stairs.⁴ Discourage the patient from reading as this will cause involuntary movement of the patched eye.

COMPLICATIONS

Infection is rare but is most likely to occur in contact lens wearers or in patients who have used a patch for a prolonged period.^{4,5,12} Patches applied too tightly can raise intraocular pressure high enough to cause retinal artery occlusion and lead to retinal ischemia, infarct, and blindness. Allergy to ophthalmic medications, the patch, or the tape materials can occur. Falls, auto accidents, and injuries due to lack of binocular depth perception can occur.^{4,5} Healing times may be prolonged with loose patches that allow movement of the eyelid over the cornea.^{4,5} The eyelashes may get caught between the eyelids and the cornea and further abrade the cornea.⁴ Eye patching has become less commonly practiced due to the above complications. Contact lens bandages can cause infective ulcerative keratitis or corneal revascularization.²⁹

SUMMARY

The eye is one of the most delicate and complex structures of the body. It is injured far more frequently than would be predicted based on its relative size.³⁵ Preservation of vision is essential to

maintaining quality of life. The cornea is one of the most sensitive organs of the body. Tiny injuries to the cornea can result in significant pain and loss of function. It is therefore essential that the Emergency Physician be skilled in vision-threatening eye injury management. The application of an eye patch or eye shield is a simple, rapid, and straightforward procedure. The improper application of these devices can result in significantly poor visual outcome.

Acute Orbital Compartment Syndrome (Retrobulbar Hemorrhage) Management

Andrew F. Perin, Jamil D. Bayram, and Sami H. Uwaydat

INTRODUCTION

Acute orbital compartment syndrome is defined as an acute elevation of intraorbital pressure with resultant rapid ocular dysfunction. Patients typically present with ocular pain, proptosis, and blurry vision (**Figure 194-1**). Clinical signs of an acute orbital compartment syndrome include afferent pupillary defects, chemosis, decreased visual acuity, diminished retropulsion of the affected globe to direct manual pressure, elevated intraocular pressure (usually above 40 mmHg), exophthalmos or proptosis, mydriasis, ophthalmoplegia, and signs of retinal ischemia on funduscopic examinations (rare).¹⁻⁴⁰

Orbital compartment syndrome has been described in multiple clinical settings. The presentation that Emergency Physicians will most likely encounter is an acute posttraumatic retrobulbar hemorrhage leading to an orbital compartment syndrome with subsequent rapid loss of vision.^{1,2} Orbital compartment syndrome has been documented following burns, aggressive fluid administration, blepharoplasty, retrobulbar anesthesia, orbital and sinus surgery, orbital fractures with intraorbital emphysema, spontaneous subperiosteal hemorrhages, and spontaneous retrobulbar hemorrhages.^{3-9,36} Orbital compartment syndrome may also occur as the result of chronic and progressive disease processes (e.g., neoplasms, infections, inflammations).¹⁰

Acute orbital compartment syndrome demands prompt recognition because irreversible loss of vision (even permanent blindness) occurs without rapid treatment.¹¹ Once the diagnosis of an acute orbital compartment syndrome is made, emergent surgical intervention is indicated. An immediate lateral canthotomy and cantholysis are indicated within 1 hour of injury and ocular dysfunction.^{32,40} Medical interventions aimed at reducing intraocular pressure (e.g., mannitol, acetazolamide, topical beta-blockers) should be considered adjunctive therapy and not a substitute for surgical intervention.

ANATOMY AND PATHOPHYSIOLOGY

The orbit is a closed space posterior to the orbital septum and contained within the bony orbit. The lateral wall of the orbit is formed by the zygomatic bone. The posterior wall is formed by the sphenoid bone. The medial wall is formed by the ethmoid bone. The roof is formed by the frontal bone. The floor is formed by the maxillary bone. The globe is enclosed in a fascial envelope within the bony orbit.

The medial and lateral canthal tendons provide structural fixation of the eyelids to the orbital rim. The lateral canthal tendon (LCT) is located posterior and inferior to the lateral canthal fold (**Figure 194-2**). The LCT originates from the superior and inferior lateral tarsal plates (**Figure 194-2**) and attaches to the lateral orbital tubercle of the zygoma (**Figures 194-2 and 194-3**). The LCT is Y-shaped and consists of a superior crus from the superior tarsal plate and an inferior crus from the inferior tarsal plate. The LCT measures 10.6 mm (standard deviation [SD] \pm 0.9 mm) in length from its attachment site to the lateral canthal angle. It is 10.2 mm

FIGURE 194-2. The lateral canthal tendon or LCT (A = the vertical height of the LCT, B = the distance from the frontozygomatic suture to the midpoint of the LCT origin, C = the length of the LCT as measured from the canthal margin to its origin).

(SD \pm 0.8 mm) in width at its origin at the lateral ends of the tarsal plates. It attaches 1.5 mm (SD \pm 0.3 mm) behind the orbital margin and approximately 9.7 mm (SD \pm 0.8 mm) below the frontozygomatic suture at the lateral orbital tubercle.¹² Immediately anterior to the LCT is Eisler's pocket, a collection of adipose tissue. Posterior to the LCT, at its attachment site to the lateral orbital tubercle, is the check ligament of the lateral rectus muscle (**Figure 194-3**). The levator aponeurosis of the upper eyelid and Lockwood's suspensory ligament of the lower eyelid also attach at the lateral orbital tubercle.

Any increase in intraorbital contents (e.g., retrobulbar hematoma, intraorbital emphysema, retrobulbar abscess) will result in an elevation of intraorbital pressure because the orbit is a closed space. Intraocular pressure elevation correlates with the degree of intraorbital pressure elevation.¹³ The globe itself may partially accommodate some of the elevation in intraorbital pressure by prolapsing forward (**Figure 194-4**). This will result in ocular pain and proptosis. The intraorbital pressure rises dramatically as the orbit approaches maximal distention. This rise in intraorbital pressure leads to chemosis, elevated intraocular pressure, and compression of the intraorbital cranial nerves. If the compression is severe enough, the patient develops an ophthalmoplegia and an afferent pupillary defect.

The exact mechanisms by which orbital compartment syndromes result in blindness remain speculative.¹⁴⁻²⁵ A common theory is that as the intraorbital pressure increases, orbital venous outflow is impeded and leads to diminished retinal and optic nerve arterial perfusion pressures. This results in an afferent pupillary defect, diminished visual acuity, and rarely fundoscopic signs of retinal ischemia. Over time, the elevated intraorbital pressure leads to irreversible optic nerve and/or retinal ischemia. Experimental studies have demonstrated that irreversible ischemic injury to the retina may occur within 90 minutes of vascular insufficiency.^{19-22,31,32,40} Additional theories suggest that direct mechanical compression or longitudinal traction on the optic nerve may contribute to the loss of vision in orbital compartment syndromes.^{23,25} Elevated intraorbital pressure may also occur from large-volume fluid resuscitation in patients without ocular trauma.³⁰

A history of progressive loss of vision following orbital trauma suggests a reversible disease process (e.g., retrobulbar hemorrhage). If loss of vision is immediate and complete following orbital trauma, the chance of recovery of vision is poor.²⁶ This is because the immediate loss of vision after trauma is due to direct optic nerve, retinal, or vascular injury rather than an orbital compartment syndrome.

Ultrasound (US) can be used to diagnose a retrobulbar hemorrhage after trauma.^{37,38} US allows quick evaluation of the orbit for a

FIGURE 194-3. An axial view of the orbital contents. Identification of the LCT will require dissection of the conjunctiva and fascial tissues with a hemostat and iris scissors. A pocket of adipose tissue (Eisler's pocket) will be encountered beneath the superficial tissue layers. The LCT lies just posterior to this adipose tissue collection.

retrobulbar hemorrhage. The patient's closed eye should be covered with Tegaderm to prevent irritation from the US gel. Use a large amount of gel so the transducer is not against the globe. Use a linear array transducer at a frequency of 7.5 to 10 MHz. The hemorrhage is anechoic or hypoechoic behind the globe. The hemorrhage is confirmed by computed tomography scan if there is time before the procedure. **An US should not be performed if one suspects or there is an actual ruptured globe.**

INDICATIONS

An acute orbital compartment syndrome is an indication for immediate orbital decompression.²⁴ Multiple case series have documented the efficacy of immediate orbital decompression in restoring visual acuity to affected patients.²⁵⁻²⁹

CONTRAINDICATIONS

Except for a ruptured globe, there are no definite contraindications to performing this procedure, as permanent loss of vision may result from untreated acute orbital compartment syndromes. The patient's

airway, breathing, circulation, and any life-threatening injuries must be addressed prior to performing this procedure. If the patient is very young, confused, or uncooperative, sedation and restraint or procedural sedation (Chapter 159) will be required to prevent iatrogenic injury to the globe.

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- Topical ocular anesthetic solution, proparacaine or tetracaine
- Lidocaine 2% with epinephrine
- 30 gauge 0.5 inch needle on a 3 mL Luer-lock syringe
- Ocular tonometer (e.g., applanation, Schiøtz, or Tono-Pen)
- Sterile saline or sterile water
- Straight mosquito hemostat
- Iris scissors
- Tissue forceps
- 2×2 gauze squares

FIGURE 194-4. A sagittal view of the orbital contents. Note the location of the retrobulbar hemorrhage.

- Topical ocular antibiotic ointment (e.g., bacitracin, ciprofloxacin, erythromycin, gentamicin, Neosporin, Polysporin, or sulfacetamide)
- #10 disposable scalpel (optional)
- Disposable hot tip cautery pen (optional)
- Desmarres retractor (optional)
- US machine (optional)
- US gel (optional)
- US transducer, linear array of 7.5 to 10 MHz (optional)
- Tegaderm (optional)

PATIENT PREPARATION

Explain the procedure to the patient and/or their representative including the risks, benefits, and outcome if it is not performed. This is a painful procedure for the awake and alert patient. Lucid patients will require parenteral medications for analgesia and sedation in addition to local anesthetics. Consider the use of procedural sedation (Chapter 159) if not contraindicated. Measure and record the visual acuity. Perform a brief ophthalmologic examination. Apply topical ocular anesthetic solution to the conjunctiva of the affected eye. Measure and record the intraocular pressure.

TECHNIQUE

Place the patient supine. Clean the eyelids and surrounding skin of any blood, dirt, and debris. Apply povidone iodine solution to the eyelids and allow it to dry. If a patient reports iodine allergy, chlorhexidine solution can be used with care to ensure it does not contact the ocular surface. **Do not let these solutions drip into the eye.** Irrigate the lateral canthal fold region with sterile saline or sterile water. Using sterile technique, identify the lateral canthal fold (Figure 194-5). Inject 1 mL of local anesthetic solution with epinephrine subcutaneously using a 30 gauge, 0.5 inch long needle on a 3 mL syringe along the lateral canthal fold. **The goal is to anesthetize the tissue extending laterally from the canthal fold to the orbital rim. Caution must be exercised to avoid inadvertent needle puncture of the globe.**

Insert a straight mosquito hemostat at the lateral canthal fold. Place one jaw of the hemostat anterior and one jaw posterior to the lateral canthal fold. Advance the tips of the hemostat laterally until the orbital rim is encountered. Clamp and compress the intervening

FIGURE 194-5. Illustration of lateral canthotomy. Iris scissors are used to cut all tissue layers along the lateral canthal fold up to the orbital rim.

tissue for approximately 1 minute. This will minimize any bleeding precipitated by the lateral canthotomy. Remove the hemostat. Cut all the tissue layers along the lateral canthal fold up to the orbital rim (lateral canthotomy) with an iris scissors (Figure 194-5). **All tissue layers, from the skin to conjunctiva, must be incised down to the orbital rim.** Use a #10 scalpel blade to cut the tissues in cases of severe distortion of the anatomy due to edema or if iris scissors are not readily available. A disposable hot cautery pen, if available, can be used to achieve hemostasis. In the setting of significant periorbital and eyelid edema, an assistant may use a Desmarres retractor to elevate the upper eyelid or separate the lids to improve exposure of the lateral canthus.

Gently grasp the cut end of the lower eyelid with a hemostat or forceps and retract it outward away from the globe. Identify the lateral canthal tendon located just posterior and inferior to the lateral canthal fold (Figures 194-2 and 194-3). The LCT can be easily identified by strumming it with the end of a closed scissors. Dissect the conjunctiva and fascial tissues with a hemostat or iris scissors. A pocket of adipose tissue (Eisler's pocket) will be encountered beneath the superficial fascial planes (Figure 194-3). The lateral canthal tendon lies just posterior to this adipose tissue collection (Figure 194-3). Completely divide the lateral canthal tendon vertically at its midportion with an iris scissors or #10 scalpel (lateral cantholysis) to transect the inferior crus of the tendon. If outward tension is kept on the lower lid with forceps during division of the LCT, there should be a notable release with successful completion of the cantholysis and the lid should separate from the globe. If unable to feel release in tension of the lid, then it is likely that only a partial cantholysis was achieved.

ASSESSMENT

A successful lateral canthotomy and cantholysis will cause an immediate decrease in intraocular pressure to less than 40 mmHg. Recheck the intraocular pressure. **If the intraocular pressure remains elevated, reexplore the lateral canthal tendon region to make sure that the inferior crus has been completely transected. If transected, cut the superior crus of the tendon to transect it.**^{34,35} Occasionally, the intraorbital and intraocular pressures will remain elevated despite successful cantholysis. These refractory cases necessitate emergent decompression of the deep orbital wall. Such decompressions call for operative techniques that are to be performed by Ophthalmologists and Otolaryngologists.

The resolution of proptosis and afferent pupillary defects and restoration of visual acuity will usually not occur immediately.³⁹ Patients who respond to surgical intervention will gradually regain their visual acuity over a period of hours to days.

AFTERCARE

Apply a topical antibiotic ointment along the canthotomy site. In orbital compartment syndromes, elevated intraocular pressures merely reflect elevated intraorbital pressures. Therefore, any attempts to decrease intraocular pressures will not reliably reduce retrobulbar optic nerve compression. Medical interventions decreasing intraocular pressure may be used following, or in conjunction with, a lateral canthotomy and cantholysis. These interventions are similar to those employed for the management of elevated intraocular pressures in patients with acute angle-closure glaucoma. This includes the use of topical beta-blockers, central acting alpha agonists, intravenous mannitol, and carbonic anhydrase inhibitors. **These medications are not a substitute for surgical orbital decompression.**

Many patients with an orbital compartment syndrome have other injuries requiring hospital admission following their

Emergency Department evaluation and treatment. Ensure a timely Ophthalmologic consultation for a complete eye exam and possible repair of the canthotomy and cantholysis sites once the orbital compartment syndrome resolves. Repair of the lateral canthal fold and lateral canthal tendon is controversial. Many Ophthalmologists do not advocate suture repair as a majority of wounds heal without complication by secondary intention. Patients with no other acute medical or surgical conditions, restored vision, a normal ophthalmologic examination, and normal postprocedural intraocular pressures may be discharged after evaluation by an Ophthalmologist.

COMPLICATIONS

Time constraints, abnormal anatomy as a result from traumatized tissue, and lack of familiarity with the lateral canthotomy and cantholysis techniques can make this a challenging procedure. Hemorrhage is often minimal and can be controlled with direct pressure. The use of a disposable cautery pen can be helpful. Mechanical injuries can include globe perforation, injury of the lateral rectus muscle, scleral lacerations, and secondary ectropion. Most of these complications can be prevented by knowing and identifying the anatomic landmarks, reviewing the procedure before it is performed, and using extreme care in performing the canthotomy and cantholysis. Despite the use of sterile technique, infections at the canthotomy and cantholysis sites can occur. They should be treated with parenteral antibiotics that cover typical skin flora.

SUMMARY

Emergency Physicians must be able to promptly recognize and be prepared to manage an acute orbital compartment syndrome defined by an acute elevation of intraorbital pressure with resultant ocular dysfunction. Patients will present with ocular pain, proptosis, an afferent pupillary defect, and diminished visual acuity. An acute orbital compartment syndrome requires emergent treatment to preserve vision. An immediate lateral canthotomy and cantholysis are indicated, preferably within 1 hour of injury and ocular dysfunction. Medical management should be considered an adjunctive therapy. Many patients will regain their visual function if the procedure is performed soon after the injury and before permanent ischemic changes occur.

Globe Luxation Reduction

Briana D. Mazur, Adam Jennings, and Heidi Knowles

INTRODUCTION

Luxation of the globe is a rare event whereby the eyelids slip behind the midcoronal plane of the eye in an extremely proptotic eye (Figures 195-1 and 195-2). Subsequent spasm of the orbicularis oculi muscle maintains the luxation of the globe. Extraocular eye

movements become severely limited. The optic nerve and retinal vasculature are subjected to an abnormal amount of traction which results in possible damage to these structures or the retina.¹ **This can result in partial or full blindness of the affected eye if it is not reduced before onset of irreversible ischemic changes.**

ANATOMY AND PATHOPHYSIOLOGY

There are three major causes of globe luxation: spontaneous, voluntary, and traumatic. Spontaneous luxation tends to occur in individuals with shallow orbits (Figure 195-1A).² Structural abnormalities

A

B

C

FIGURE 195-1. Globe luxations. **A.** Spontaneous luxation. Note the eyelids behind the midcoronal plane of the eye and the lacrimal gland in front of the eyelids. (Used with permission from www.clinicalgate.com.) **B.** Voluntary luxation. **C.** Luxation associated with forceps delivery. (Used with permission from reference 16.)

FIGURE 195-2. The luxated globe. **A.** Superior view. **B.** Lateral view.

(e.g., anomalous extraocular muscles, laxity of the supporting fascia, and laxity of the supporting muscles) can predispose to spontaneous luxation.²⁻⁴ Pathologic processes that can cause proptosis can predispose to luxation. The literature documents cases of luxation associated with cerebral gummas, chronic obstructive pulmonary disease, craniofacial dysostosis, Cushing's syndrome, floppy eyelid syndrome, Graves' disease, histiocytosis X, and orbital tumors.^{1,5-9} Voluntary luxation occurs in individuals who learn to cause globe propulsion by using a digit or their extraocular muscles (**Figure 195-1B**). Some patients use a Valsalva maneuver to luxate their globe(s) voluntarily.

Traumatic luxation results from injury to the globe or the surrounding bony orbit.^{10,11} It can occur from motor vehicle accidents or relatively minor trauma to the face.^{12,13} Traumatic luxation can be associated with complete avulsion of the optic nerve. Traumatic luxation can occur from intentional eye gouging or during the forceps-assisted delivery of a neonate (**Figure 195-1C**).¹⁴⁻¹⁶

The normal anatomic relationship of the globe to the surrounding structures is seen in **Figure 195-3**. The midcoronal plane of the globe is through the widest portion of the eye and divides it into anterior and posterior halves. The eyelids get behind the midcoronal plane of subluxed globes, the orbicularis oculi muscle is pulled

taut, and the orbicularis oculi muscle begins to go into spasm. This spasm prevents spontaneous reduction of the eye.

INDICATIONS

Globe reduction is indicated to relieve traction on the optic nerve and retinal vessels. The visual acuity may be compromised without prompt reduction. Sustained globe luxation is physically and psychologically uncomfortable for the patient, may result in permanent loss of vision, and is often difficult to reduce without general anesthesia. **Attempt to reduce all globe subluxations if an Ophthalmologist is not immediately available.**¹⁷

CONTRAINDICATIONS

Rupture of the globe and extensive orbital fractures that require immediate surgical intervention are relative contraindications to globe reduction. Edema and retrobulbar hemorrhage can make reduction outside the Operating Room difficult or impossible.^{1,9} Consult an Ophthalmologist for globe subluxations that cannot be reduced, when procedural sedation is contraindicated, or when the patient is uncooperative.

FIGURE 195-3. Anatomy of the eye and orbit.

EQUIPMENT

- Topical ocular anesthetic agent (e.g., 0.5% proparacaine or tetracaine)
- Sterile gauze and gloves
- Sutures or eyelid retractors
- Local anesthetic solution if eyelid retaining sutures need to be placed
- 3 mL syringe
- 27 gauge needle

PATIENT PREPARATION

Perform a directed eye examination (Chapter 185) addressing the integrity of the globe, visual acuity, pupillary reactivity, and range of ocular motion prior to any attempt at reduction. Explain the risks, benefits, and alternative procedures to the patient and/or their representative. Describe the procedure and answer any questions. Obtain an informed consent for the procedure and place this in the medical record. When performing the procedure on a neonate or child, it is advisable to give the parent the option to leave the room or look away as the procedure can be disconcerting to some parents.

Relaxation of the patient and the orbicularis muscles is essential for procedural success. The use of a parenteral analgesic, parenteral anxiolytic, or procedural sedation (Chapter 159) is recommended if not contraindicated.¹⁸ Place the patient supine. Instill a topical ocular anesthetic agent onto the affected eye. Allow 1 to 2 minutes for the anesthetic to take full effect.

TECHNIQUE

Reduction of a globe luxation ideally requires two people (Figure 195-4).^{18,19} Instruct an assistant to apply steady upward and outward traction on the upper eyelid and downward and outward traction on the lower eyelid by grasping and pulling on the eyelashes. Instruct the patient to maintain a constant downward

FIGURE 195-4. Reduction of a globe luxation.

gaze. The downward gaze posture negates the retracting action of the levator palpebrae superioris muscle and simultaneously relaxes the superior rectus muscle.¹⁹ Apply steady and gentle pressure with a gloved thumb to the exposed superior sclera of the globe in a simultaneously downward and posterior direction while traction is being applied to the eyelids. Physical contact over the sclera minimizes discomfort and avoids possible corneal abrasions.¹⁹ Continue to apply constant and gentle pressure until the globe is manipulated back into the orbit.^{1,9}

ALTERNATIVE TECHNIQUE

The patient's eyelashes are occasionally small or not accessible, or an assistant is not available. Place an eyelid retractor behind the eyelids to provide countertraction. Other authors have recommended the placement of a suture through the anesthetized skin of the eyelids to help retract them.^{1,4,9} **Extreme care must be taken to prevent penetration of the globe by the anesthetic needle or the suture needle if retaining stitches are placed in the eyelids.** The globe is then reduced in the same manner as described previously.

ASSESSMENT

A repeat and complete eye examination must be performed after the procedure and documented in the medical record. Pay special attention to visual acuity, pupillary reflexes, and range of extraocular muscle movement.^{1,9,15} Full visual acuity may not return to baseline for several days or longer.⁴ Initiate a search for the possible causes of a nontraumatic luxation in the Emergency Department.^{1,5,8,9} This includes but is not limited to thyroid function testing and orbital imaging to rule out a tumor. Perform this evaluation after consultation with an Ophthalmologist. Conduct a search for associated injuries (e.g., bony periorbital fracture, globe rupture, intracranial injury, or a retro-orbital hematoma) in traumatic luxations.

AFTERCARE

Discharge patients with spontaneous luxations that reduce without difficulty and who are without visual impairment after consultation with an Ophthalmologist. These patients require follow-up with the Ophthalmologist within 24 hours.^{1,9} Instruct the patient to avoid Valsalva maneuvers and any triggering actions (e.g., aggressive eyelid manipulation while inserting contact lens).¹ All patients with traumatic luxation require emergent Ophthalmologic consultation and imaging of the orbits.^{1,9} Treat any corneal abrasions.

COMPLICATIONS

It is common for eyelashes to be retained in the conjunctival fornices after the reduction.¹⁵ Perform a thorough evaluation and remove any free eyelashes to prevent corneal abrasions or eye injury.^{1,9,15} Instill saline drops to the eye and apply an eye shield (Chapter 193) to prevent further injury while an emergent Ophthalmologic consult is obtained if one or two attempts at reduction are not successful.^{1,9} Reducing an open globe (i.e., when known or unknown) can expel the eye contents and make vision loss permanent. **Always perform an eye examination before reducing any luxation. Place an eye shield and consult an Ophthalmologist if there is any question of a globe perforation.**

SUMMARY

Globe luxation is a rare entity that can be effectively dealt with in the Emergency Department. Prompt intervention by an Emergency Physician can result in the preservation of visual acuity. Perform a brief initial eye examination. Uncomplicated cases can be reduced

by the Emergency Physician. Complicating factors (e.g., the presence of trauma, an open globe injury, or the inability to reduce the globe) require an emergent Ophthalmologic consultation. Investigate any predisposing factors for a spontaneous luxation.

Hordeolum (Stye) Incision and Drainage

Sami H. Uwaydat, Andrew F. Perin, and Jamil D. Bayram

INTRODUCTION

A hordeolum is a suppurative infection of one of the eyelid glands.¹⁻¹⁵ The nomenclature that describes infectious and inflammatory conditions of the eyelid glands is at times confusing. A brief description of the eyelid margin anatomy may help resolve some of the confusion. The patient usually presents with an acutely painful, erythematous, localized, and tender mass on either the upper or lower eyelid. A hordeolum may be associated with a blepharitis.

ANATOMY AND PATHOPHYSIOLOGY

The eyelid is composed of numerous structures (**Figure 196-1**). The eyelid skin is thin and vascular. The orbicularis oculi muscle encircles the eyelids and controls their movements. The hair follicles that form the eyelashes are fine and delicate in comparison to hair on other body areas. Numerous glands are contained within the eyelids. The glands of Zeis are modified sebaceous glands associated with the hair follicles. The glands of Moll are modified sweat glands that open into the base of the hair follicles. The tarsus is a rigid fibrous plate containing the sebaceous Meibomian glands. The orifice of the elongated Meibomian glands can be seen posterior to the eyelashes at the eyelid margin. The thin and delicate conjunctiva lines the inner aspect of the eyelids.

A hordeolum can be located internally or externally in relation to the eyelid and tarsal plate. It is essentially an abscess of the eyelid. An internal hordeolum is a bacterial infection of the Meibomian gland and usually points to the inside or conjunctiva (**Figure 196-2**). An internal hordeolum is usually larger than an external hordeolum. If the infection blocks the neck of the Meibomian gland, the infection points toward the conjunctival surface of the eyelid. If the neck of the Meibomian gland is not blocked, the infection often points to the eyelid margin. An external hordeolum, also known as a stye, is a bacterial infection of the glands of Zeis or Moll. These tend to be small, superficial, and point to the eyelid skin or, more commonly, the eyelid margin. The most common causative agent in both internal and external hordeola is *Staphylococcus aureus*.¹ Other infectious agents and conditions can be the etiology.¹⁵

Patients with a hordeolum almost always present with localized pain, redness, and swelling of the eyelid margin. It is usually a benign process but can progress to a preseptal or septal cellulitis. It may rarely result in a corneal epithelial defect,² periorbital necrotizing fasciitis,³ and bacteremia.⁴

A chalazion is a chronic (lasting > 2 weeks) granulomatous inflammation of a sebaceous Meibomian gland. Acute chalazion lesions, those less than 2 weeks old, are often difficult to distinguish from an acute hordeolum. Clinically, the management of an acute chalazion and an acute hordeolum are the same and it is not necessary to differentiate the two processes. A chalazion may persist for many months and slowly enlarge over time. A chronic chalazion is characterized by a painless localized swelling of the eyelid margin with no inflammatory signs. It feels rubbery upon palpation. A chronic chalazion does not require an urgent intervention and should be managed by an Ophthalmologist. A chalazion that is acute, large, or causes local irritation may require incision and drainage. Recurrent chalazia require an evaluation by an Ophthalmologist to rule out a malignancy.

MANAGEMENT

Hordeola are initially managed conservatively.¹³ Warm compresses should be applied over the eyelid for 10 to 15 minutes at a time three to six times per day. An alternative and portable solution to warm compresses would be to place 8 to 10 ounces of dry rice in a sock and heat it in a microwave (typically for 30 seconds). The rice tends to maintain the heat for a longer period compared to the warm compresses. Apply diluted baby shampoo to the eyelid margins with a washcloth or cotton-tipped applicator for daily eyelid scrubs. Topical antibiotic ointments (e.g., erythromycin) can be placed in the conjunctiva or on the eyelid margin three times per day. The purpose of topical antibiotics is to prevent the infection from spreading to adjacent hair follicles. Oral antibiotics are indicated only if the signs and symptoms of a cellulitis develop. Most hordeola will spontaneously drain and resolve within 5 to 7 days with conservative management. Treat any accompanying blepharitis to prevent the formation of additional hordeola.

FIGURE 196-1. Eyelid margin anatomy. The type and location of the infected gland determines whether it is an internal hordeolum or an external hordeolum (stye).

INDICATION

Surgical excision is warranted if the hordeolum does not resolve with conservative management and the patient has significant discomfort. A hordeolum can be excised if it causes a cosmetic deformity, blocks the visual axis, or is of a significant size.

CONTRAINDICATIONS

Not all hordeola should be incised and drained in the Emergency Department. Hordeola close to the lacrimal puncti or the medial canthus are best managed conservatively until surgery can be coordinated with an Oculoplastic surgeon. Drainage in patients on blood thinners and in those who are unable to follow commands is contraindicated. Sedation is required for children, the confused patient, and the uncooperative patient. Consult an Ophthalmologist prior to sedating a patient to incise and drain a hordeolum. A recurrent hordeolum should be referred to an Ophthalmologist for

biopsy and evaluation of the lesion for a malignancy.¹⁴ Consult an Ophthalmologist prior to the procedure if the hordeolum affects visual acuity or ocular movements.

EQUIPMENT

- Buffered local anesthetic solution (e.g., lidocaine with epinephrine and NaHCO_3)
- 30 gauge, 0.5 inch needle on a 3 mL syringe
- 0.5% proparacaine drops
- Povidone iodine or chlorhexidine swabs
- Small drape with central opening
- Sterile 4×4 gauze squares
- Sterile cotton-tipped applicators
- Sterile marking pen
- Corneal Eye Shield or Morgan lens (Chapter 187, Mortan Inc., Missoula, MT)
- #11 or #15 scalpel blade on a handle
- Westcott scissors
- Desmarres chalazion clamps, multiple sizes
- Meyerhoefer chalazion curettes, multiple sizes
- Castro-Viejo forceps
- Low-temperature disposable cautery unit
- Topical ophthalmic antibiotic ointment without steroids (e.g., erythromycin)
- Eye pad
- Culture swabs
- 1-inch tape

A chalazion clamp is a device specifically designed to aid in the incision and drainage of a chalazion or hordeolum (**Figure 196-3**).

FIGURE 196-2. An internal hordeolum with redness and swelling.

FIGURE 196-3. The chalazion clamp.

It is similar to a forceps except the distal ends are expanded and it has a clamp mechanism. One of the distal ends is an open circle used to surround the hordeolum. The other distal end is flat, solid, and acts to prevent injury to underlying structures. Just proximal to the distal expanded ends is a screw mechanism that allows the distal ends to be closed and clamped securely in place.

PATIENT PREPARATION

Perform a brief ophthalmic examination including visual acuity, motility, and an anterior segment assessment. Document the size and location of the hordeolum. Explain the procedure, its risks, and benefits to the patient and/or their representative. Place a signed informed consent in the medical record. Many patients are apprehensive when a surgical procedure is performed close to their eye. It is imperative that the patient remains still during this procedure given that sharp instruments will be exchanged over the globe. A

FIGURE 196-4. Incision and drainage of a hordeolum. **A.** The hordeolum is identified and a circle is drawn around its margins. A needle is inserted to inject local anesthetic solution. **B.** Local anesthetic solution is injected into and around the hordeolum. **C.** A chalazion clamp is applied and an incision is made over the hordeolum. **D.** Purulent material is expressed from the incision using a chalazion curette. **E.** Inflammatory tissue is removed.

thorough explanation of the surgical steps should alleviate some of the patient's fears. Consider the use of parenteral sedation or procedural sedation (Chapter 159).

Place the patient supine. Support their head with a headrest or a foam doughnut. Place one drop of proparacaine in the cul-de-sac of the affected eye. Mark the circumference of the hordeolum with a sterile skin marker (**Figure 196-4A**). This is important as the injection of local anesthetic solution will obscure the margins of the hordeolum. Gently wipe the eyelid skin with an alcohol swab. **Do not allow the alcohol to get onto the eye.** Clean the skin of the eyelid with povidone iodine or chlorhexidine solution. **Do not allow these solutions to get onto the eye.** If any solution does get onto the eye, irrigate the eye copiously with normal saline. Arm a 30 gauge needle onto a 3 mL syringe. Draw up 1 mL of buffered local anesthetic solution with epinephrine. Inject the solution around and into the hordeolum (**Figures 196-4A and 196-4B**). **Direct the syringe tangential to the skin (for an external hordeolum) or conjunctiva (for an internal hordeolum) so as to avoid inadvertent penetration of the globe.** Place a corneal shield or Morgan lens (Chapter 187), if available, over the cornea.

TECHNIQUES

INTERNAL HORDEOLUM

Cleanse and anesthetize the area as described above. Apply a chalazion clamp to the eyelid. Place the loop of the clamp on the

conjunctival surface of the eyelid and encompassing the marked edges of the hordeolum (**Figure 196-4C**). Place the plate of the clamp on the skin surface of the eyelid. Gently close the clamp by turning the screw mechanism. Gently flip the clamp to expose the hordeolum. Make a superficial cruciate incision in the hordeolum with a #11 or #15 scalpel blade (**Figures 196-4C and 196-4D**). Gently insert the chalazion curette to scoop out the purulent material (**Figure 196-4D**). Alternatively, use a sterile cotton-tipped applicator. Grasp the edge of the inflammatory tissue with the Castro-Viejo forceps. Carefully use Westcott scissors to dissect the planes between the hordeolum and the tarsus (**Figure 196-4E**). Release the chalazion clamp and gently remove it from the eyelid. Bleeding may occur as the clamp is released. Careful application of low-temperature cautery can be used to achieve hemostasis. Alternatively, apply gentle pressure with a gauze square to the incision to control any bleeding. **Be careful to not touch the eye with the gauze and cause a corneal abrasion.** Culture the expressed purulence. Place ophthalmic erythromycin ointment in the cul-de-sac. Apply a pressure patch over the eye (Chapter 193).

EXTERNAL HORDEOLUM

Cleanse and anesthetize the area as described above. Make an incision over the hordeolum with a #11 or #15 scalpel blade. **Do not cut the eyelid margin or the underlying tarsus.** Gently roll a sterile cotton-tipped applicator over the eyelid skin and toward the incision to express the purulent material. Apply gentle pressure with a gauze square to the incision to control any bleeding. **Be careful to not touch the eye with the gauze and cause a corneal abrasion.** Culture the expressed purulence. Place ophthalmic erythromycin ointment on the eyelid skin. Apply a pressure patch over the eye (Chapter 193).

ASSESSMENT

Palpate the eyelid at the end of the procedure. If a residual pus collection is detected, attempt to express the pus with a cotton-tipped applicator. If this fails, a second incision parallel to the first one is required to completely drain the hordeolum. **Do not undermine the delicate eyelid tissues to express the purulent material.** While not required, some physicians may perform a repeat fluorescein examination to ensure that they did not cause a corneal abrasion during the procedure.

AFTERCARE

The follow-up instructions are simple and straightforward. Instruct the patient to remove the pressure patch in 1 to 2 hours. It was placed to minimize any edema and bleeding from the procedure. If significant bleeding is noted when the patch is removed, the patient should immediately return to the Emergency Department. They should apply a warm compress (or warm rice in a sock) to the eyelid every 3 to 4 hours for the first 24 hours. An eyelid skin incision should remain clean and dry for 24 hours. Prescribe topical ophthalmic antibiotic ointment (e.g., erythromycin if no contraindications exist) to be applied on the skin incision or in the cul-de-sac three times a day for 3 to 4 days. Someone must follow-up on the cultures results in 12 to 24 hours. If methicillin-resistant *S. aureus* (MRSA) is detected, the patient must be notified and they require follow-up with an Ophthalmologist within 24 hours or return to the Emergency Department for the consideration of oral antibiotics. Treat any associated blepharitis to prevent the formation of a new hordeolum.

The patient should follow up with an Ophthalmologist within 5 to 7 days for an evaluation of the eyelid. They need to be evaluated sooner if the cultures are positive for MRSA. They should immediately be seen by an Ophthalmologist or return to the Emergency

Department if any of the following develop: uncontrollable bleeding, increase in eyelid pain and/or swelling, the appearance of yellow or green pus in the eye or on the eyelid, and fever.

Oculoplasty referral is warranted to evaluate recurrent hordeolum and chalazion to rule out malignancy.^{5,14} Recurrent bilateral hordeola may indicate an underlying immunodeficiency (e.g., immunoglobulin M).⁶

COMPLICATIONS

Numerous complications are possible both during and as a result of the incision and drainage procedure. Inadvertent injury to the globe (e.g., corneal abrasion or corneoscleral perforation) or eyelid structures (e.g., lacrimal duct or punctum) may occur.⁷ Early complications include infections such as a cellulitis or conjunctivitis. Most bleeding can be controlled with gentle pressure or tying off of the offending vessel with fine absorbable sutures. Careful and gentle portable cautery can be applied to control bleeding but extensive cautery can lead to excessive eyelid scarring. Uncontrolled bleeding is rare but can occur and will require an Ophthalmologist to control. Late complications occur from excessive scarring at the incision site. If an external incision was made, the contracting scar can lead to an ectropion, eyelid retraction, uneven eyelid margins, and trichiasis. Maintaining a vertical incision perpendicular to the eyelid margin mitigates the risk of future eyelid malposition. If an internal incision was made, conjunctival scarring can lead to an entropion and chronic conjunctivitis.

SUMMARY

Patients with an acute hordeolum often present to the Emergency Department with a painful, localized, red, and swollen eyelid margin. They should be initially managed conservatively. Subsequent incision and drainage may be required to alleviate the patient's discomfort. The incision and drainage procedure is simple to perform and can be done by the Emergency Physician.

External Auditory Canal Foreign Body Removal

G. Carolyn Clayton, Katarzyna M. Gore, and
Melissa M. Rice

INTRODUCTION

Foreign bodies are commonly found in the external auditory canal (EAC) of children and sometimes in adults.¹ Children commonly place small objects such as food (e.g., beans, peas, corn, and seeds) or small round objects (e.g., beads, rocks, and toys) in the EAC.²⁻⁶ Adults are more likely to suffer from items used to clean or scratch the ear (e.g., cotton swab, paper, paper clips, and pencil lead) and insects that crawl into the ear.^{4,6} The EAC and tympanic membrane (TM) are exquisitely sensitive and delicate.^{3,7} Foreign bodies in the EAC are extremely irritating to patients, especially live insects that scratch the TM trying to escape. **Injuries can occur unless proper care is taken in the removal of EAC foreign bodies.**

ANATOMY AND PATHOPHYSIOLOGY

The EAC is an S-shaped structure that extends from the auricle to the TM and is approximately 2.5 cm long in adults.^{8,9} The lateral or distal third is cartilaginous with thick skin. It has more hair follicles, glands, and subcutaneous tissue than the medial or proximal two-thirds of the EAC. The medial EAC is bony with a thinner and more fragile layer of skin.⁸⁻¹¹ The narrowed isthmus of the EAC is located between the cartilaginous and bony portions.^{2,8} The EAC ends medially at the TM. The TM is angled obliquely to increase the surface area for carrying sound energy to the middle ear.¹⁰ The anteroinferior EAC is 0.6 mm longer than the posterosuperior portion.⁸ Auriculotemporal branches of cranial nerves V, VII, IX, and X and the greater auricular nerve of the cervical plexus supply sensation to the EAC.⁸ The EAC and TM have separate innervation. Indications for anesthetizing these areas are distinct from those for performing an auricular block (Chapter 156). The posterior auricular, superficial temporal, and deep auricular arteries provide the blood supply to the external ear. The posterior auricular and superficial temporal veins drain the EAC. The posterior auricular vein can connect to the sigmoid sinus and provide a route for spread of infection between the ear and the intracranial cavity.⁹

INDICATIONS

All EAC foreign bodies must be removed. The questions are how quickly this must be done, who should do it, and which is the safest technique. The method used is individualized to the patient, type of foreign body, Emergency Physician preference and experience, and the availability of an Otolaryngologist. **The most urgent indication for immediate removal is an alkaline button battery because of the extensive and severe damage it may cause in a very short time.**^{1,12}

Some foreign bodies are very easily and safely removed with the equipment available in any Emergency Department. Other foreign bodies may require removal under general anesthesia by an Otolaryngologist. Remove foreign bodies that are in the lateral half of the EAC, graspable, light or small, and have space around the foreign body for inserting an instrument. Things that make removal difficult are caustic foreign bodies, EAC blood, EAC edema, foreign bodies in the EAC for >24 hours, foreign bodies that touch the TM, and proinflammatory foreign bodies. Other foreign bodies (e.g., those that are impacted, involved with the TM or middle ear structures, large in size, or in young or mentally disabled patients, or have sharp edges) will require removal under general anesthesia or via a surgical approach.^{2,7,13,14}

CONTRAINDICATIONS

These can be thought of as indications for referral to an Otolaryngologist for removal of the foreign body rather than contraindications to removal. The major contraindication to removal in the Emergency Department is probable injury with direct removal (e.g., foreign bodies located in the middle ear or those that have perforated the TM). Removal may cause further damage to the TM as well as potential disruption of the middle ear ossicles and hearing loss. These foreign bodies require removal under general anesthesia with the aid of an operating microscope.^{2,3,5,13} Another contraindication is a large object that has impaled itself in the wall of the EAC. Direct removal will require anesthesia and possibly a surgical approach from outside the EAC to avoid denuding the skin of the EAC.³ Refer patients with foreign bodies that are difficult to remove or patients who cannot hold still for the procedure (e.g., mentally disabled patients or young children) to an Otolaryngologist.^{2,5,13,15} These cases are likely to result in injury if the foreign body is removed in the Emergency Department.

Irrigation is almost always safe to attempt with some critical exceptions.¹⁶ One such contraindication is button battery removal.^{1,12} There are two mechanisms for the rapid destruction of surrounding tissues by the batteries. The moisture and cerumen in the EAC have a high conductivity. This causes conduction of electric current from the battery and results in localized electrical burns. Local inflammation from burns will cause fluid exudation into the EAC. This increases the electrical conduction injury and causes the battery to begin leaking alkaline electrolyte solution with resultant liquefaction necrosis.^{3,17} The degree of damage may be dependent on the remaining voltage in the battery, its chemical composition, its location, and the duration of mucosal exposure.^{3,17,18} **Irrigation with water or saline is contraindicated in button battery removal and another technique must be used.**¹

Another important contraindication for irrigating the EAC is an acute or chronically ruptured TM.^{13,16,19-21} Water forced into the middle ear can lead to disruption of the ossicles, labyrinthitis, loss of balance, loss of hearing, mastoiditis, and otitis media. Some authors recommend alternate methods for any patient who has never had an ear exam to document the integrity of the TM.^{13,16,19} Completely impacted foreign bodies that leave no space for the irrigant fluid to

flow behind it will be driven deeper into the EAC making subsequent removal more difficult.^{1,22}

A relative contraindication for irrigation with water is an organic object (e.g., dry bean, seed, or rice) or toy expanding beads.²²⁻²⁶ Organic foreign bodies will absorb water and swell making removal more difficult. Irrigation can be attempted if the foreign body is very small and irrigation is expected to rapidly succeed in removal before swelling occurs. Irrigate the foreign body with alcohol, remove it with instruments, or extract it with suction.

Directly grasping the foreign body with forceps is contraindicated for large or spherical objects that will not allow clear passage of the forceps jaws along its sides. Attempts to grab this type of foreign body will drive it deeper into the EAC.^{22,27}

EQUIPMENT

■ ANESTHESIA

- 1%, 2%, or 4% lidocaine solution or gel
- 1 mL syringe
- 5 mL syringe
- 27 or 30 gauge needle
- EAC speculum

■ IRRIGATION

- 10 or 20 mL syringe
- Butterfly catheter with the needle and most of tubing cut off
- Plastic portion of 18 gauge angiocatheter
- Kidney basin
- Chux or other water barrier
- Tap water or saline at or slightly above body temperature^{7,10,16,20,21}

■ ALTERNATE IRRIGATION EQUIPMENT¹⁰

- Plastic portion of 18 gauge angiocatheter
- Dental jet irrigation device (e.g., Water-Pik)
- DeVilbiss irrigator and a compressed air source
- Metal ear syringe

■ INSTRUMENTS TO PASS BEHIND FOREIGN BODY AND PULL IT OUT (FIGURES 197-1 TO 197-4)

- Ear curettes or cerumen spoon (e.g., disposable plastic or metal)
- Wire loop
- Blunt or ball right-angle hook

■ INSTRUMENTS USED TO GRASP FOREIGN BODY DIRECTLY (FIGURES 197-1 AND 197-3)

- Alligator forceps
- Hartman forceps
- Lighted device (Bionix Medical Technologies, Toledo, OH)

■ SUCTION

- Frazier suction tips (Figure 197-1E)
- Schuknecht catheter
- Intravenous tubing with flange created at tip using a heat source
- Vacuum or suction source
- Connection tubing
- Hemostat

FIGURE 197-1. Instruments used for removal of foreign bodies from the external auditory canal. **A.** Cerumen loop. **B.** Right-angle ball hook. **C.** Alligator forceps. **D.** Hartman forceps. **E.** Frazier suction catheter.

■ CYANOACRYLATE GLUE²⁸

- Ear speculum
- Cyanoacrylate tissue adhesive
- Cotton-tipped applicator
- Cyanoacrylate removal equipment

■ CYANOACRYLATE TISSUE ADHESIVE REMOVAL²⁹

- Acetone to debond glue from skin
- Cotton balls
- Cotton-tipped applicators
- Irrigation or instruments for final removal

■ MAGNET REMOVAL

- Pacemaker magnet
- Metallic medical instrument
- Household magnet

FIGURE 197-2. Examples of plastic disposable curettes. Note the variety of head shapes. (Photo courtesy of Bionix Medical Technologies, Toledo, OH.)

FIGURE 197-4. The EasiEar metal curette (Splash Medical Devices LLC, Atlanta, GA.)

COMMERCIALLY AVAILABLE DEVICES

- Hognose otoscope tip
- Gatornose otoscope tip
- Katz Extractor
- OtoClear Ear Irrigation Tip

PEDIATRIC IMMOBILIZATION

- Sheets
- Commercial immobilization device (e.g., Papoose board)

PATIENT PREPARATION

Explain the risks, benefits, and alternative procedures to the patient and/or their representative. The discussion should include discomfort, dizziness, minor bleeding, postprocedural otitis externa, and TM perforation. **Discuss the importance of remaining still during the procedure.**²⁷ Warn the patient that they may experience an occasional loud noise, especially if suction is used. Obtain an informed consent for the procedure and place this in the medical record.

The most convenient position for adult patients is to remain seated with the affected ear facing the Emergency Physician. Children can sit on the lap of a parent or attendant with the affected ear facing the Emergency Physician. The parent or attendant should wrap one arm around the child's arms and body while stabilizing the head with their other arm (**Figure 197-5**).³ Smaller children can be swaddled in a

FIGURE 197-5. A parent holding a child.

papoose made from a sheet and tape or a commercial immobilization device (Chapter 232).³ Place the patient supine with their face toward the ceiling. **Do not place the patient with the affected ear facing up as this may cause the foreign body to move farther into the EAC.**

All removal techniques require the EAC to be straightened before inserting any device. This is accomplished in the older child, adolescent, and adult by pulling the pinna up and back while simultaneously pulling it straight out from the head.¹⁰ Pull the pinna down, back, and slightly out from the head in the small child.^{7,10}

The patient may require anesthesia of the EAC. Fill the EAC with 5 to 10 mL of 1% lidocaine using the syringe tip, an angiocatheter without the needle, or a butterfly catheter with the needle cut off. This will result in substantial but short-lived topical anesthesia for the procedure.²² The topical application of lidocaine can be repeated as needed or longer-acting agents may be used if the effect wears off before the procedure is complete.

Injection of local anesthetic solution is usually not necessary. It may be required in some patients. Fill a 1 mL syringe with local anesthetic solution and apply a 2 inch long, 27 or 30 gauge needle. Position a plastic or metal ear speculum into the EAC. Insert the needle through the speculum. Inject 0.25 mL subcutaneously in the superior and inferior quadrants of the EAC distal to the isthmus. All four quadrants can be injected if needed.^{22,23} Refer to Chapter 156 for a complete discussion of EAC anesthesia. A final option is to use procedural sedation and analgesia (Chapter 159) to control the patient and remove the foreign body.³⁰

TECHNIQUES

PRECAUTIONS FOR USING INSTRUMENTS IN THE EAC

There are two major precautions to avoid pushing the foreign body further into the EAC, causing damage to the EAC, or causing damage to the TM. **The procedures must be performed under direct vision. The hand holding the instruments must remain firmly in contact with the patient's head to stabilize the hand to avoid abrading the EAC, lacerating the EAC, or damaging the TM if the patient abruptly moves.**^{2,10} A very cooperative patient may move due to an involuntary reflex cough.⁷

IRRIGATION

Irrigation is the safest method of foreign body removal.^{2,10,13,31} It is most successful for nonimpacted and smaller foreign bodies. **Be sure to use only body temperature or slightly warmer fluid to avoid complications from caloric stimulation.**^{10,16} Tuck a water

barrier into the patient's gown or collar. Place a kidney basin under the ear and against the cheek to catch the irrigation solution and the foreign body. Instruct the patient or an assistant to hold the basin in place. Attach a butterfly needle to a 10 or 20 mL syringe. Cut the needle and most of the tubing from the butterfly leaving only 1 to 2 cm of the tubing (**Figure 197-6**). The remaining tubing will usually be curved which is optimal for precisely directing the irrigation stream. An alternative is to use a 14 or 16 gauge plastic angiocatheter.³² **Wider diameter instruments deliver fewer pounds per square inch of pressure with a reduced chance of injury.**³²

Draw up body temperature or slightly warmer tap water or saline into the syringe. Straighten the EAC by manipulating the pinna. Insert the butterfly tubing or angiocatheter 1 cm into the EAC with the tip aimed upward and away from the foreign body (**Figure 197-6**).²⁰ Rapidly inject the irrigating solution. This will cause the fluid to shoot past the foreign body, bounce off the TM, and carry the foreign body out of the EAC along with the irrigating solution.^{2,13}

Care must be taken to make sure that the irrigation stream and foreign body can easily exit the EAC to prevent an increase in hydrostatic pressure which could damage the TM.¹⁹ Sometimes irrigation will not completely remove the foreign body but move it more laterally where an instrument can be safely used to grasp and remove it. Remove all water or saline from the EAC when done to prevent otitis externa.^{10,16}

Many physicians have used mechanical dental irrigation devices (e.g., Water-Pik) to irrigate the EAC and remove either cerumen or a foreign body. These devices shoot a stream of fluid from its tip. The direct fluid stream can rupture a TM.^{16,32,33}

The OtoClear Ear Irrigation Tip (Bionix Medical Technologies, Toledo, OH) is an improvement for EAC irrigation (**Figure 197-7A**). This device is designed as disposable and single patient use. It attaches to the Luer hub of a syringe. The OtoClear tip can be attached to a spray bottle or dental irrigating device or bought from Bionix (**Figure 197-7B**). This allows these devices to be safely used. The flared base of the OtoClear fits snugly and prevents it from being inserted too far into the EAC. Holes in the base of the OtoClear allow for the egress of irrigation fluid into the basin held against the skin. The OtoClear tip directs fluid toward the walls of the EAC and prevents damaging the TM (**Figure 197-7B, inset**). The OtoClear may not provide enough flow or pressure in some cases to remove a foreign body.

SLIDING A FOREIGN BODY OUT WITH AN INSTRUMENT FROM BEHIND

This technique requires either a cerumen spoon or wire loop for small objects or a right-angle hook for larger ones (**Figures 197-1**

FIGURE 197-6. Irrigation with butterfly catheter tubing attached to a syringe. The stream of fluid is aimed toward the top of the external auditory canal and above the foreign body.

FIGURE 197-7. The Bionix OtoClear. **A.** The device. **B.** The device on a spray bottle and an irrigation device. The reusable basin on the left slips on the base of the spray bottle or irrigation device for storage and can be used to catch the irrigating solution. The inset shows the irrigation solution coming out the tip of the OtoClear. (Photos courtesy of Bionix Medical Technologies.)

through 197-4). Straighten the EAC by manipulating the pinna. Pass the tip of the instrument over and behind the foreign body with the spoon, loop, or hook in the same plane as the EAC wall. Rotate the instrument 90° to bring the loop or hook behind and directly in

FIGURE 197-8. The Bionix lighted forceps for foreign body removal with a magnification lens. (Photo courtesy of Bionix Medical Technologies.)

contact with the back (medial) side of the foreign body. Gently pull the instrument out of the EAC and pull the foreign body out with it.^{2,10} **Take extra care so that the EAC and TM are not injured during the instrument insertion or removal.**

The EasiEar Disposable Comfort Curette (Splash Medical Devices LLC, Atlanta, GA) is an improvement to the standard disposable plastic curette (**Figure 197-4**). It is a stainless steel, single patient use, and disposable curette. The rounded wire head is smooth. It lacks the jagged and sharp plastic edges that are often found on molded plastic curettes. The EasiEar has no abrasive edges, seams, or surfaces to potentially abrade the EAC. This design may prevent EAC abrasions, bleeding, and lacerations. The spring wire shaft provides flexibility and enhanced maneuverability when compared to molded plastic curettes. The angled head and flexible shaft allow it to be manipulated within the EAC to remove a foreign body.

GRASPING FOREIGN BODIES WITH FORCEPS

There must be sufficient space between the EAC wall and the foreign body or a projecting edge that can be grasped to avoid pushing it further into the EAC.^{2,4,11,13} This technique is contraindicated if the object is spherical and located against the TM. The TM can be injured during the procedure.^{4,27} The most commonly used instruments include the alligator forceps (**Figure 197-1C**) and the Hartman forceps (**Figure 197-1D**). Lighted forceps (Bionix Medical Technologies, Toledo, OH) may be used (**Figures 197-3 and 197-8**).

Straighten the EAC by manipulating the pinna. Insert the forceps into the EAC and grasp the foreign body (**Figure 197-9**). Gently withdraw the instrument and the foreign body. Take care not to abrade the EAC wall. Irrigation may be able to move the foreign body laterally for subsequent grasping if the foreign body is located too far medially or instrumentation would cause pain or damage to the TM.

FIGURE 197-9. Forceps removal of a foreign body. **A.** Hartman forceps. **B.** Alligator forceps.

SUCTION REMOVAL

Frazier suction catheters (**Figure 197-1E**) are most successful with small foreign bodies. Attach the Frazier suction catheter to the suction tubing. Turn on the suction source. Straighten the EAC by manipulating the pinna. Gently insert the catheter into the EAC. Place a thumb over the hole in the catheter handle to direct the suction through the tip of the catheter. Gently advance the suction catheter until its tip is in contact with the foreign body. Withdraw the Frazier suction catheter with the attached foreign body from the EAC. The Schuknecht catheter functions similarly to a Frazier suction catheter. It has a small, central, retractable stylus that can be helpful in grasping foreign bodies with a central opening.¹¹

Suction with plastic intravenous tubing can be used for impacted smooth spherical objects.^{1,34} Cut a short length of plastic intravenous tubing and attach one end to the suction source. Fashion the other end into a small flange using a heat source and any metal object with a rounded end (e.g., the tip of a hemostat or larger clamp). Heat the jaws of the hemostat and insert them into the plastic tubing just enough to create a flange. Turn on the suction source. Place a hemostat onto the tubing to temporarily clamp the suction tubing. Straighten the EAC by manipulating the pinna. Gently advance the flange tip into the EAC until it contacts the foreign body taking care not to push it inward (**Figure 197-10**). Have an assistant remove the hemostat from the tubing to activate the suction. Gently but quickly remove the tubing and attached foreign body from the EAC.

The Bionix Suction Removal Device (**Figure 197-11A**) is used to remove foreign bodies. It is a plastic, disposable, single-use device that contains a magnification lens. The device attaches to portable suction or low wall suction (**Figure 197-11B**). Removal of the foreign body is described above.

CYANOACRYLATE TISSUE ADHESIVE ASSISTED REMOVAL

Cyanoacrylate tissue adhesive can be used to extract impacted spherical objects that allow no space for irrigation or instrument removal.^{1,28} This technique can be fraught with complication.²⁹

Always use an ear speculum to decrease the chance of gluing the foreign body to the EAC or TM and to prevent creating a glue foreign body. Insert an ear speculum into the EAC with the tip near the foreign body. **Do not touch the foreign body with the speculum to prevent it from being impacted.** The ear speculum will prevent the

FIGURE 197-10. Suction removal of a foreign body.

A

B

FIGURE 197-11. The Bionix lighted suction removal device. **A.** The device. **B.** The device attached to a portable suction unit. (Photos courtesy of Bionix Medical Technologies.)

Emergency Physician from touching the EAC with cyanoacrylate tissue adhesive.

Obtain a cotton-tipped applicator. Moisten the tip of the applicator stick with a very tiny amount of cyanoacrylate tissue adhesive. A larger amount can drop off into the EAC. Insert the ear speculum. Straighten the EAC by manipulating the pinna. Quickly insert the applicator stick through the ear speculum before the cyanoacrylate tissue adhesive dries. Advance the stick until it just touches the foreign body. Maintain this position for 30 to 60 seconds to allow bonding of the cyanoacrylate tissue adhesive to the foreign body. Remove the applicator stick with the foreign body attached and the speculum together.

REMOVAL OF CYANOACRYLATE TISSUE ADHESIVE

Debonding glue from the patient's tissues with acetone must precede the foreign body removal for iatrogenic or patient-introduced cyanoacrylate adhesive.^{1,29,35} Failure to do this will result in tearing of the skin or TM when the dried cyanoacrylate is removed. **Do not apply acetone if the TM cannot be visualized or is not intact.**¹⁶ Infuse acetone into the EAC using cotton balls or swabs. Allow it to

remain in the EAC for 5 minutes. Several applications may be necessary since acetone evaporates rapidly. The glue mass can be removed by irrigation, instruments, or suction once it is free.

MAGNET REMOVAL

Attempt removal using magnets when the foreign body is magnetic.^{34,36-38} One method includes magnetizing a medical instrument (e.g., forceps or hemostat) by placing it in series with a pacemaker magnet. Place the instrument in the EAC to attract the metallic foreign body. Another method is to use a household magnet at the entrance of the EAC in attempts to attract the foreign body. The strength of the magnet and the distance to the foreign body may limit this method.^{24,36}

HOGNOSE OTOSCOPE TIP

The Hognose (IQDr. Incorporated, Manitou Springs, CO) is a disposable, latex free, and single-use device that attaches to a standard otoscope (**Figure 197-12**). It comes in three sizes (i.e., 3, 4, and 5 mm) with a color-coded tip. The size represents the cup size at the tip of the device. The tip is soft, self-molding, and looks like the nose of a hog. It has an insufflation port and suction tubing attached to its side. The adapter on the suction tubing attaches to standard wall suction tubing.

Attach the Hognose to the otoscope as if attaching a disposable speculum to an otoscope. Turn on the otoscope light source. Attach the hognose tubing to suction tubing and a suction source. Turn the suction source to low or medium. Grasp the otoscope with the dominant hand. Straighten the EAC by manipulating the pinna. Insert the Hognose into the EAC while visualizing the foreign body through the otoscope head. Place an index finger over the insufflation port to engage the suction when the tip of the Hognose is just next to the foreign body. Gently advance the otoscope until the tip of the Hognose is against and attached to the foreign body. The soft

FIGURE 197-12. The Hognose otoscope tip attached to an otoscope. (Photo courtesy of IQDr. Incorporated, Manitou Springs, CO.)

tip has collapsed on itself if black is visible through the otoscope. Remove the finger over the insufflation port and reapproach the foreign body. Withdraw the Hognose with the foreign body attached while maintaining suction.

GATORNOSE OTOSCOPE TIP

The Gatornose (IQDr. Incorporated, Manitou Springs, CO) is a disposable, latex-free, and single-use device that attaches to a standard otoscope (**Figure 197-13**). It twists onto an otoscope like a speculum. It comes with three different jaw types that attach to the body of the device. These jaws are small flat jaws, large flat jaws, and open loop jaws. A trigger on the body of the device controls jaw opening and closing.

Attach the Gatornose to the otoscope as if attaching a disposable speculum to an otoscope. Select the appropriate jaws and attach these to the Gatornose base attached to the otoscope. Turn on the otoscope light source. Grasp the otoscope with the dominant hand. Insert the ring finger into the trigger. Pull the trigger to close the Gatornose jaws. Straighten the EAC by manipulating the pinna. Gently insert the Gatornose jaws just into the EAC. Push the trigger to open the Gatornose jaws and view through the otoscope. Gently advance the otoscope while visualizing the foreign body through the otoscope head. Position the jaws above and below or anterior and posterior to the foreign body. Pull the trigger to close the jaws onto the foreign body. Withdraw the otoscope with the foreign body in the jaws of the Gatornose.

KATZ EXTRACTOR

The Katz Extractor Oto-Rhino Foreign Body Remover (InHealth Technologies, Carpinteria, CA) is a device designed to extract foreign bodies from the nasal and auditory passages (**Figure 197-14**). It is a disposable single-use device consisting of a balloon-tipped catheter attached to a syringe. Always test the device before using it. Push the plunger to inflate the balloon and inspect it for any air leaks. Release the plunger to deflate the balloon.

Grasp the device with the dominant hand (**Figure 197-15**). Gently insert the catheter along the wall of the EAC until the balloon is just past the foreign body (**Figure 197-15A**). Inflate the balloon by depressing the plunger on the syringe (**Figure 197-15B**). Withdraw

FIGURE 197-13. The Gatornose otoscope tip attached to an otoscope. Note the three types of jaws that are available to snap onto the base of the device. (Photo courtesy of IQDr. Incorporated, Manitou Springs, CO.)

FIGURE 197-14. The Katz Extractor. The balloon at the tip inflates and deflates by pushing and releasing the plunger, respectively. (Photo courtesy of InHealth Technologies, Carpinteria, CA.)

the catheter and foreign body from the EAC while maintaining the balloon in the inflated state (**Figure 197-15C**). Insert the catheter through the hole rather than behind it if the foreign body has a central hole (e.g., candy or bead).

LIVE INSECT REMOVAL

A live insect in the EAC is one of the most painful and upsetting foreign bodies. The patient suffers as the insect moves, vibrates, tries to flap its wings, or pushes against the sensitive TM to escape.³ The Emergency Physician may attempt removal by turning off the main room lights and using a small source light near the EAC to lure the insect out.¹⁴ Many substances have been tried to kill live insects in the EAC.^{3,4,9,22,39}

The preferred technique is to immobilize the insect with an infusion of 1% lidocaine into the EAC.⁴⁰ A topical anesthetic composed of benzocaine and antipyrine (e.g., Auralgan) may be used. The local anesthetic results in the insect becoming inert much quicker than with mineral oil. The EAC and TM are anesthetized for patient comfort and the immobilized insect is more likely to be removed in a single piece than with mineral oil.

The insect can now be easily removed by irrigation or instrument removal. Sometimes both techniques are used. Irrigation can be used to move the dead insect more distally in the EAC followed by instrument removal. Irrigate and inspect the EAC after the insect is removed to make sure that no tiny parts of the insect remain in the EAC which can cause otitis externa.³

Mineral oil was infused in the past to smother and kill the insect prior to its removal.^{4,22,40} This method has several disadvantages. A significant time passes while the patient is still suffering and the insect dies. The insect is more difficult to remove from the viscous oil and frequently breaks into multiple pieces. It is impossible to subsequently anesthetize the EAC with topical lidocaine which is repelled by the mineral oil.

ASSESSMENT

Reexamine the patient to confirm that the EAC, TM, and hearing are all normal and have not been damaged after the foreign body has been removed.^{3,4,31} It is prudent to examine the other ear, the nostrils, and any other orifice that may be harboring an unsuspected foreign body in children, patients with mental disabilities, or patients with psychiatric problems.³⁻⁵ Remove any remaining irrigation fluid in the EAC to prevent otitis externa.¹⁰

AFTERCARE

Consider prescribing several days of topical otic drops to prevent or treat subclinical otitis externa which is often precipitated by an abrasion of the EAC or inflammation due to foreign body

FIGURE 197-15. The Katz Extractor removing an EAC foreign body. **A.** The device is inserted until the balloon is just past the foreign body. **B.** The balloon is inflated. **C.** The device is removed with the balloon inflated and the foreign body is removed.

impaction.³ Often recommended are topical combinations of antibiotics and steroids (e.g., Cortisporin otic or Ciprodex). Consult an Otolaryngologist for patients with injuries, hearing deficits, severe otitis externa, or in whom foreign body removal was unsuccessful.⁴¹ The patient can follow-up with their Primary Care Physician in 48 to 72 hours after removal of the foreign body. Instruct the patient or their caregiver in the proper application of ear drops. The patient

should return to the Emergency Department if they develop ear pain, ear discharge, fever, decreased hearing, headache, stiff neck, or vertigo.

COMPLICATIONS

Numerous complications can result from the removal of a foreign body from the EAC.^{3-5,10,16,19,21,22,31} The complication rate for irrigation is reported as 1 per 1000 cases.^{21,31} It is higher for all other techniques.^{10,16} Irrigation can push a foreign body further into the EAC. Caloric stimulation of cold irrigating solution can result in bradycardia, syncope, vertigo, and vomiting.^{1,16} Middle ear debris can be forced through a preexisting or iatrogenic TM defect resulting in central nervous system infections, damage to the ossicles, labyrinthitis, loss of hearing and balance, mastoiditis, or otitis media.^{13,16,19-21} Otitis externa can result from abrasions to the EAC or water left behind after irrigating. Butterfly tubing is less likely than an angiocatheter to damage the EAC or TM because of its more pliable nature, larger diameter, and curved tip.

Mechanical dental irrigation devices can rupture the TM.^{16,32,33} This can occur at low pressures. These devices are not recommended for the removal of foreign bodies from the EAC.

Use instrumentation and suction with caution to prevent secondary injury. This includes EAC abrasions, EAC lacerations, disruption of the ossicles, infection, pushing of foreign bodies further into the EAC, and TM rupture.²⁷ Abrasions or lacerations to the EAC can result in mastoiditis, meningitis, or otitis externa. A foreign body in the EAC can lead to these infectious complications.

Cyanoacrylate tissue adhesive can cause complications and should be used with caution. The Emergency Physician may glue their fingers together or to the instruments. The foreign body may be glued to the pinna, EAC, or TM. Removal of the cyanoacrylate can cause abrasions, irritate the skin, and irritate the TM.

SUMMARY

Foreign bodies in the EAC are common. Most foreign bodies can be successfully removed in the Emergency Department from the EAC with adequate anesthesia, careful planning, and gentle handling.⁴³ The removal techniques require equipment that is readily available in the Emergency Department. The removal techniques are easy to perform, quick, and simple to learn. An impacted button battery is a true emergency and requires immediate removal. An emergent consultation with an Otolaryngologist is required if the button battery cannot be removed or if any evidence of injury is present after the button battery has been removed.

Cerumen Impaction Removal

Dayle Davenport

INTRODUCTION

Removal of impacted cerumen (**Figure 198-1**) is one of the most common otolaryngologic procedures performed by physicians who are not Otolaryngologists.¹ It is also a common cause of iatrogenic otolaryngologic complications with medical malpractice suits that frequently result in payment.² Approximately 150,000 ears are irrigated weekly and 8 million annually in the United States to remove cerumen.^{3,4}

ANATOMY AND PATHOPHYSIOLOGY

The S-shaped external auditory canal (EAC) is 2.5 cm long in adults.⁵ The lateral or distal third is cartilaginous, with thicker skin, more hair follicles, glands, and more subcutaneous tissue than the medial or proximal two-thirds which is bony and has a thinner, more fragile

FIGURE 198-1. Cerumen from the external auditory canal on a cotton-tipped applicator. (Used from www.commonswiki.org/wiki/File:Earwax_on_swab.jpg.)

layer of skin.^{5,6} The narrowed isthmus is located between the cartilaginous and bony portions.⁵ The canal ends medially at the tympanic membrane (TM) which is situated obliquely to increase the surface area for carrying sound energy to the middle ear.⁵ The anteroinferior EAC is 0.6 mm longer than the posterosuperior portion.⁵ Auriculo-temporal branches of cranial nerves V, VII, IX, and X and the greater auricular nerve of the cervical plexus supply sensation to the EAC.⁵

Cerumen (**Figure 198-1**) is a mixture comprising secretions of the ceruminous glands of the lateral two-thirds of the EAC, the pilo-sebaceous glands located at the roots of EAC hairs, and sloughed squamous epithelial cells.^{5,7} Cerumen forms a barrier against infection, has antimicrobial activity, and protects the skin of the EAC as it is water repellent. It is expelled naturally by migration and assisted by chewing movements.^{7,8}

There are many reasons for cerumen to become impacted.^{4,7} The most common is self-cleaning with cotton-tipped applicator swabs that can push cerumen further into the EAC (**Figure 198-1**). The abundant hairs in the EAC, more common in males than females, can obstruct cerumen migration. A small (e.g., especially in children), tortuous, or scarred EAC will obstruct cerumen migration. Some people produce large quantities of cerumen. Diseases such as Parkinson's can alter the consistency of the cerumen and inhibit its migration. Hearing aids, earbud headphones, stethoscope earpieces, or any other object in the EAC may compact the cerumen. Deficits in the substances that cause sloughed squamous epithelial cells to separate will inhibit the movement of cerumen. Nonimpacted cerumen exposed to water can swell and obstruct the EAC.

INDICATIONS

The term "impaction" is defined as cerumen that causes patient symptoms or prevents a necessary examination of the EAC or TM, even without complete obstruction of the canal.⁴ The primary indication for removal of cerumen is the symptomatology of impaction.⁴ The most common complaint is hearing loss which is often abrupt and expressed as a "blocked ear." Hearing remains normal or nearly so as long as there is a small space in the EAC through which sound can pass and cause vibration of the TM. The hearing loss becomes subjectively significant when the canal is completely obstructed or when the TM is compressed by cerumen and cannot freely move.^{4,8} Other typical symptoms of cerumen impaction include fullness, itching, odor, pain, tinnitus, vertigo, unsteady gait, or reflex cough due to vagus nerve stimulation.^{4,7} Other indications for removing cerumen include the need to examine the ear canal, to examine the TM, or to test the patient's hearing.^{4,8,9} Cerumen can cause feedback sound loops in those with hearing aids or damage the appliance.⁴

CONTRAINDICATIONS

There are several general contraindications to cerumen removal. An uncooperative patient or young patient who cannot follow instructions or be safely restrained can suffer an iatrogenic injury. Previous ear surgery or radiation therapy to the ear with scarring of the EAC or TM risks iatrogenic injury. A known or suspected cholesteatoma is a contraindication to cerumen removal. Do not attempt removal if the anatomy of the EAC or TM cannot be clearly defined or is distorted.

The remaining contraindications to cerumen removal are specific to each removal technique. Nearly all cerumen can be safely removed by using one of the techniques listed. Often, two or more techniques can be used together with increased success.⁹

The most important contraindication for EAC irrigation is an acute or chronically ruptured TM.^{4,7-12} Fluid forced into the middle ear can lead to otitis media, labyrinthitis, mastoiditis, disruption of the ossicles, and loss of balance or hearing.^{4,10,12} Some authors

recommend alternate methods for any patient who has never had an ear examination to document the integrity of the TM.^{9,10} Most patients can provide the information of having a history of a ruptured TM. A relative contraindication is moderate to severe otitis externa.^{4,7,8}

The major contraindication to instrument removal of cerumen is a patient, usually pediatric, who is so uncooperative that injury to the EAC or TM is likely to occur with movement.^{12,13} The second contraindication is cerumen pushed directly against the TM. In these circumstances, the TM can be abraded or perforated during cerumen removal with instruments.

The major contraindication to suction removal is a single, hard, irregular, and impacted cerumen plug as suction will be unsuccessful. Suction works best if there are multiple tiny cerumen fragments or very soft cerumen.⁹

Cerumen softening or cerumenolytic agents should not be used if the patient has a ruptured TM. Other contraindications to softening agents are an allergy to the agent or otitis externa.^{4,7,14,15}

EQUIPMENT

■ IRRIGATION

- 10 to 20 mL syringe
- Butterfly catheter with any size needle
- Kidney basins
- Chux (or other water barrier)
- Tap water or saline at or slightly above body temperature⁵

■ ALTERNATE IRRIGATION EQUIPMENT⁴

- Plastic portion of an 18 gauge angiocatheter
- Oral jet irrigation (i.e., Water-Pik) no longer recommended (see below)³
- DeVilbiss irrigator and a compressed air source
- Metal ear syringe

■ INSTRUMENTS TO SEPARATE AND LOOSEN CERUMEN (FIGURES 198-2 TO 198-5)

- Ear curettes or cerumen spoon, metal or disposable plastic
- Wire loop
- Blunt or ball right-angle hook

■ INSTRUMENTS TO GRASP CERUMEN DIRECTLY (FIGURES 198-2 AND 198-4)

- Alligator forceps
- Hartman forceps
- Lighted forceps (Bionix Medical Technologies, Toledo, OH)

■ SUCTION

- Frazier suction catheters
- Suction source
- Connection tubing
- Hemostat

■ CERUMEN-SOFTENING AGENTS

- Warm tap water
- Saline solution
- Hydrogen peroxide
- Olive, mineral, vegetable, or almond oil

FIGURE 198-2. Instruments used for removal of cerumen from the external auditory canal. **A.** Cerumen loop. **B.** Right-angle ball hook. **C.** Alligator forceps. **D.** Hartman forceps. **E.** Frazier suction catheter.

- 5%, 10%, or 15% sodium bicarbonate solution
- Commercial agents (e.g., Cerumenex, Cerumol, Auralgan, Waxesol)
- 10% triethanolamine polypeptide oleate condensate
- Carbamide peroxide (i.e., Debrox)
- Colace
- Glycerin
- Alcohol
- Propylene glycol

■ PEDIATRIC IMMOBILIZATION

- Sheets
- Commercial immobilization device (e.g., Papoose board)

PATIENT PREPARATION

Explain the risks, benefits, and potential complications of the procedure to the patient and/or their representative. **The discussion should include discomfort, dizziness, minor bleeding, postprocedural otitis externa, and TM perforation. Discuss the importance of remaining still during the procedure.** Warn the patient that they may experience an occasional loud noise, especially if suction is used. Obtain a signed consent for the procedure. Some Emergency Physicians omit the signed consent and place the following statement in the procedure note: "The risks, benefits, and complications were described and discussed with the patient. They understood this and gave verbal consent for the procedure." This decision must be based on physician preference, hospital guidelines, and state guidelines for documentation requirements.

The most convenient position for adult patients is to remain seated with the ear facing the Emergency Physician. Children can sit on the

A

B

FIGURE 198-3. Examples of plastic disposable curettes. **A.** The curettes. **B.** Note the variety of head shapes. (Photo courtesy of Bionix Medical Technologies, Toledo, OH.)

lap of a parent or attendant with the affected ear facing the Emergency Physician. The parent or attendant should wrap one arm around the child's arms and body while stabilizing the head with their other arm (Figure 197-5). Smaller children can be swaddled in a papoose made from sheets and tape or a commercial immobilization device.¹⁶

Most patients do not require topical anesthesia. Occasionally, a patient will require it. Turn the affected ear toward the ceiling and fill the EAC with 5 to 10 mL of local anesthetic solution or suspension using the syringe tip, an angiocatheter, or a butterfly catheter with the needle cut off. This will result in substantial but short-lived topical anesthesia for the procedure. The topical application of local anesthetic can be repeated as needed or longer acting agents may be used if the effect wears off before the procedure is complete.

All cerumen removal techniques require the EAC to be straightened. This is accomplished by grasping the pinna and pulling it slightly up and back while simultaneously pulling it straight out from the head in the older child, adolescent, and adult.⁶ Pull the pinna down, back, and slightly out from the head in the young child.^{6,17}

FIGURE 198-4. Lighted, disposable, and single patient use devices to aid in cerumen removal. From left to right: lighted placement tool, lighted ear curette, lighted forceps for foreign body removal, articulating curette, and lighted suction removal device. (Photo courtesy of Bionix Medical Technologies, Toledo, OH.)

TECHNIQUES

PRECAUTIONS FOR USING INSTRUMENTS IN THE EAC

There are two major precautions the Emergency Physician must take to avoid pushing cerumen further into the EAC or causing damage to the EAC and TM. **First, the procedures must be performed under direct vision.**⁶ **Second, the hand holding the instrument must remain firmly in contact with the patient's head at all times to stabilize the hand and avoid scrapping the canal wall or puncturing the TM should the patient move.**^{6,15} Even a very cooperative patient may move due to an involuntary reflex cough.¹⁷

IRRIGATION

Irrigation is the safest and easiest method of removing cerumen and is usually successful.^{2,4,6,10,15} Removal is facilitated by the use of water or a cerumenolytic for 15 to 30 minutes prior to irrigation.¹⁸ It is less likely to lacerate or damage the EAC or TM than other techniques. It is also the technique most commonly used by physicians who are not Otolaryngologists.

Place a kidney basin under the affected ear and against the patient's cheek to catch the exiting irrigation solution and cerumen. Instruct

FIGURE 198-5. The EasiEar metal curette (Splash Medical Devices LLC, Atlanta, GA.)

FIGURE 198-6. Irrigation with butterfly catheter tubing attached to a syringe. The stream of fluid is aimed toward the top of the external auditory canal and above the cerumen.

the patient or an assistant to hold the basin in place. Cut a butterfly needle to remove the wings and needle and allow only 1 to 2 cm of tubing to remain to improvise an irrigation system (**Figure 198-6**).¹³ This remaining tubing will usually be curved which is optimal for precisely directing the irrigation stream. Alternatively, a 14 or 16 gauge plastic angi catheter can be used.¹² It is important to remember that wider diameter instruments deliver fewer pounds per square inch of pressure with a reduced chance of injury.¹² Attach the irrigation tubing or angi catheter onto a 10 or 20 mL syringe (**Figure 198-6**). Draw up body temperature or slightly warmer normal saline or tap water into the syringe to prevent a caloric-reflex response.⁴ Insert the butterfly tubing or angi catheter 1 cm into the EAC with the tip aimed in a direction opposite to the location of the cerumen (**Figure 198-6**).⁸ This will cause the water to shoot past the cerumen, bounce off the TM, and force the cerumen out of the EAC along with the irrigating solution.¹⁰ Direct the stream superiorly or slightly anterior and superiorly if there is no obvious break in the cerumen.^{4,10} **Instill the stream gently and check the EAC intermittently for clearance of cerumen. Stop immediately if the patient experiences pain, bleeding, or vertigo.**¹⁹

Care must be taken to make sure that the irrigation stream can easily exit the EAC to prevent an increase in hydrostatic pressure which could damage the TM.⁹ Irrigation will often have to be repeated numerous times but persistence is usually rewarded with success.⁶ Irrigation will sometimes have to be combined with cerumen-softening agents, manual separation of cerumen from the EAC wall, or direct grasping of a partially dislodged cerumen plug.^{4,6}

Many physicians have used mechanical dental irrigation devices (e.g., Water-Pik) to irrigate the EAC and remove cerumen. These devices shoot a stream of fluid from its tip. While they will often remove the cerumen, the direct fluid stream can rupture a TM.^{3,4,12,20,21}

The OtoClear Ear Irrigation Tip (Bionix Medical Technologies, Toledo, OH) is another method for EAC irrigation (**Figure 198-7**). This device is designed as disposable and single patient use. It attaches to the Luer hub of a syringe. The OtoClear tip can also be attached to a spray bottle or dental irrigating device, allowing these devices to be safely used. When inserted into the EAC, its flared base fits snugly and prevents it from being inserted too far. Holes in the base allow for the egress of irrigation fluid and cerumen into the kidney basin held against the skin. The OtoClear tip directs fluid toward the walls of the EAC (**Figure 198-7**) and away from the TM, theoretically reducing damage to the TM.²²

Commercial devices are available for the irrigation of cerumen from the EAC. Two of the devices are the Aural Irrigation System and the Ear Wash System (Welch Allyn, Skaneateles Falls, NY).²³ They attach to a standard sink faucet to provide a regulated flow of

continuous water. The water flows from the sink through the unit to a hand-held piece held in the EAC. These types of devices are rarely available in the Emergency Department.

INSTRUMENT REMOVAL: SEPARATION OF CERUMEN FROM THE EAC WALL

This technique is a useful adjunct to irrigation and/or instrument removal.¹⁵ Sometimes the cerumen is firmly pressed against the EAC wall in all visible directions. Irrigation will not work or may even worsen the situation by pushing the cerumen further into the EAC. Use either cerumen curettes (**Figures 198-3 to 198-5**), loops (**Figure 198-2A**), right-angle hooks (**Figure 198-2B**), or wires to gently separate the cerumen from the EAC wall and compress it into the center of the lumen.⁹

The EasiEar Disposable Comfort Curette (Splash Medical Devices LLC, Atlanta, GA) is an improvement to the standard disposable plastic curette (**Figure 198-5**). It is a stainless steel, single patient use, and disposable curette. The rounded wire head is smooth and lacks the jagged and sharp plastic edges that are often found on molded plastic curettes. The EasiEar has no abrasive edges, seams, or surfaces to potentially abrade the EAC. This design may

FIGURE 198-7. The OtoClear Ear Irrigation Tip. (Photo courtesy of Bionix Medical Technologies, Toledo, OH.)

prevent painful cerumen removal, EAC abrasions and lacerations, and procedure-related bleeding. The spring wire shaft provides some flexibility and enhanced maneuverability when compared to molded plastic curettes making the cerumen removal process easier.

The best place to start is superiorly as the superior portion of the cerumen plug tends to be thinner.²⁴ **The cerumen should not be pulled out with the same movement as this can abrade the EAC.**¹⁵ Once there is a visible passage to the TM, irrigation as described above is highly successful and safe. Alternatively, separation of the cerumen from the EAC wall can be performed circumferentially all the way around the cerumen plug. This results in a cerumen plug freely suspended in the EAC that can easily be removed by irrigation, pulled out with a right-angle hook, or grasped with forceps.¹⁵

INSTRUMENT REMOVAL: SLIDING CERUMEN OUT WITH INSTRUMENTS FROM BEHIND

This technique requires either a cerumen spoon (Figure 198-2A), a wire loop for small cerumen particles, a right-angle hook (Figure 198-2B) for larger quantities, or an EasiEar curette (Figure 198-5). Separate the cerumen from the EAC wall as described above. Position the instrument with the loop or hook in the same plane as the EAC wall. Insert the tip of the instrument into the EAC above and just beyond the cerumen to be removed. Rotate the instrument 90° to bring the loop or hook behind and directly in contact with the back (i.e., medial) side of the cerumen. Gently pull the instrument out of the EAC, pulling the cerumen out with it.²⁴ **Take care not to abrade the EAC wall with the instrument.**

INSTRUMENT REMOVAL: GRASPING CERUMEN WITH FORCEPS FOR REMOVAL

There must be sufficient space for the jaws of the forceps on both sides between the EAC wall and the cerumen or a lateral leading edge that can be grasped. Separate the cerumen from the EAC wall as described above. Insert the forceps into the EAC with the blades closed and taking care not to push the plug further back in the ear. When the obstruction is encountered, grasp the cerumen with the jaws of the Hartman (Figure 198-8A) or alligator forceps (Figure 198-8B).²⁴ Gently withdraw the forceps taking care not to abrade the EAC wall. If the cerumen is located too far medially or instrumentation would cause pain or damage to the TM, irrigation can move the cerumen plug laterally for subsequent grasping with forceps.

The Emergency Physician may need to alternate irrigation and instrument removal to remove all of the cerumen plug safely and

FIGURE 198-9. Suction removal of cerumen.

completely.^{4,6} For example, irrigation may gently soften or loosen the plug. A cerumen loop or curette can then be used to separate it from the EAC wall. Irrigation can be used again to move it more laterally. Finally, a forceps or hook can be used to remove the cerumen plug from the EAC.

SUCTION REMOVAL

This technique requires soft cerumen or multiple small flakes.⁹ Use the same preparations and precautions described above. Attach the Frazier suction catheter or suction tubing to the suction source. Turn on the suction source. Insert the suction catheter into the EAC. Gently advance the suction catheter until the tip is in contact with the cerumen (Figure 198-9). If using a Frazier suction catheter, place the thumb over the hole on the catheter shaft to direct the suction through the tip of the Frazier catheter. Gently advance the Frazier catheter until its tip is in contact with the cerumen. Withdraw the suction catheter or Frazier catheter and cerumen from the EAC. Usually the tip must be withdrawn and cleaned continuously as most cerumen will plug the suction tip. For additional safety, insert the suction catheter through a plastic otoscope speculum and withdraw both together.

A relatively new device is available from Bionix (Figure 198-10). The Lighted Suction device (Bionix Medical Technologies, Toledo, OH)

FIGURE 198-8. Forceps removal of cerumen. A. Hartman forceps. B. Alligator forceps.

FIGURE 198-10. A disposable, lighted, single-use suction curette containing a magnification lens. (Photo courtesy of Bionix Medical Technologies, Toledo, OH.)

is an economical, plastic, single-use, and disposable device. It has the advantage of providing its own light. It attaches to wall suction or portable suction through an adapter built in to the handle. The built-in magnifying lens helps the Emergency Physician see the walls of the EAC and TM very easily.

CERUMEN-SOFTENING AGENTS

Apply a “cerumenolytic” or cerumen-softening agent if the cerumen is so impacted and hard that the above techniques are likely to cause pain, are likely to cause injury, or if the cerumen cannot be removed.¹⁸ After the cerumen has softened, it can be removed using the techniques described above. Many studies have compared different agents and most are surprisingly comparable in their effectiveness.^{1,4,7,14,18,25-27} In fact, even water or saline is effective for cerumen softening and disintegration.^{1,4,7,14,25-27} This may explain why persistent irrigation is so frequently successful. The more commonly available agents in the Emergency Department are listed in the “Equipment” section.

Fill the EAC with one of the cerumen-softening agents. Insert a cotton ball into the opening of the EAC to prevent the agent from leaking out. Apply the agent to the contralateral EAC if indicated. An alternative is to place the patient lying on their side with the affected ear facing upward. Insert the agent into the EAC. The agent will not leak out if the patient remains in this position. The disadvantage of placing the patient on their side is that only one ear can be worked on at a time.

Most authors recommend waiting 15 to 30 minutes after the application of the cerumen-softening agent before attempting to remove the cerumen.^{8,18} Some recommend using the agents at home for up to a week before further removal attempts.^{8,9} Prolonged exposure to these agents can precipitate otitis externa, allergic reactions, or a contact dermatitis in the EAC. These agents must be removed and the canal thoroughly dried after their use.⁴

ASSESSMENT

It is critical to reexamine the ear to confirm that the EAC, TM, and hearing are all normal after the cerumen has been removed.^{2,4} Remove all remaining water and softening agents to prevent otitis externa.⁴

AFTERCARE

Many authors recommend prescribing several days of topical otic drops to prevent or treat subclinical otitis externa which is frequently present in these patients. Often recommended are topical

combinations of antibiotics and steroids in solution or suspensions. Commonly prescribed agents include otic quinolones, Corticosporin Otic, Otic Domeboro, Otobiotic, Pediotic suspension, and VoSol, to name a few. Consult an Otolaryngologist for patients with injuries, hearing deficits, severe otitis externa, or in whom cerumen removal was unsuccessful. Otherwise, the patient can receive follow-up with their Primary Care Physician in 48 to 72 hours. Instruct the patient in the proper application of ear drops. They should return to the Emergency Department if they develop ear pain, ear discharge, fever, decreased hearing, vertigo, headache, or a stiff neck. They should also be cautioned against future use of cotton swabs or other instruments in the EAC.

COMPLICATIONS

Numerous complications can result from the removal of cerumen from the EAC. These include but are not limited to perforation of the TM, otitis externa, damage to the external canal, deafness, vertigo, and tinnitus.^{2-4,7,9,12,13,20,26,27} The complication rate for irrigation is 1 per 1000 cases.^{2,4,7} Irrigation can push cerumen further into the EAC. Irrigation fluid must be body temperature or slightly warmer. Cold fluid can cause caloric stimulation resulting in vertigo, vomiting, bradycardia, or syncope. Middle ear debris can be forced through a preexisting or iatrogenic TM defect resulting in an otitis media, ossicle damage, labyrinthitis, mastoiditis, loss of hearing and balance, or a central nervous system infection. Otitis externa can result from abrasions to the EAC or retained fluids. Butterfly tubing is less likely than an angiocatheter to damage the EAC or TM because of its more pliable nature, larger diameter, and curved tip.

It is known that mechanical dental irrigation devices, even at low pressures, can rupture the TM. For this reason, they are not recommended for cerumen removal.^{3,4,12,21}

Instrumentation and suction should be used with caution to prevent secondary injury. This includes lacerations or abrasions of the EAC, rupture of the TM, pushing foreign bodies further into the EAC, and disruption or removal of the ossicles. Abrasions or lacerations to the EAC can result in otitis externa.

Cerumen-softening agents can cause a contact reaction in the EAC and may lead to otitis externa. If the TM is not intact, these agents may cause permanent middle ear damage. Do not use these agents if the TM is ruptured acutely or the history suggests a potential defect.

SUMMARY

Successful cerumen removal will often require using multiple techniques in sequence and adapted to the individual patient's situation. Removal of cerumen requires adequate anesthesia, careful planning of the procedural sequence, and gentle handling. Those who have been relieved of a cerumen impaction will be among your most grateful patients.

FIGURE 199-1. Tympanocentesis of the right ear. The patient is lying supine with their head directed to the left. **A.** An ear speculum is inserted into the external auditory canal. A needle is inserted through the posterior inferior quadrant of the tympanic membrane to aspirate middle ear fluid. **B.** Magnified view of the tympanic membrane.

in their practice guidelines for AOM. Many authors are calling for culture-directed antibiotic therapy for otitis media to reduce the need for broad-spectrum antibiotics and prevent the emergence of multiresistant organisms.²⁻⁷

ANATOMY AND PATHOPHYSIOLOGY

The ear is divided into the external, middle, and inner parts. The external ear is comprised of the auricle, the external auditory canal, and the external auditory meatus. The middle ear contains an air space and mastoid cells ventilated by the eustachian tube, the tympanic membrane, and the three ossicles. The inner ear is comprised of the cochlea, semicircular canals, fluids, and cranial nerve VIII. The facial nerve courses through the middle ear space and mastoid process. It can be affected by a severe infection in these areas. Facial asymmetry during an acute ear infection is an indication of an unusually severe infection.

Inspection of the tympanic membrane will usually show it to be bulging during an acute infection with loss of mobility on pneumatic otoscopy. Conditions that are more chronic may show color changes of the tympanic membrane. There may be associated scarring and distortion.

INDICATIONS

Tympanocentesis is performed to obtain fluid for microbiological culture and antibiotic sensitivity testing to determine the infectious cause of a middle ear effusion.¹ Tympanocentesis is warranted for patients with AOM that is severe or unresponsive to conventional antimicrobial therapy for 48 to 72 hours or in a child less than 8 weeks of age to rule out gram-negative organisms. Tympanocentesis is warranted for

199

Tympanocentesis

Paul J. Jones

INTRODUCTION

Tympanocentesis, first described in 1768, is a diagnostic and therapeutic procedure in which a needle is inserted through the tympanic membrane to aspirate fluid from the middle ear (**Figure 199-1**). The procedure is considered diagnostic when the material obtained is sent for laboratory and/or microbiological analysis. It is considered therapeutic in most instances because it relieves pressure, reducing pain, and often shortens the course of acute otitis media (AOM).

The procedure is quick, simple, and not as frequently performed as it should be. General practitioners and Pediatricians would frequently perform the procedure for the relief of pain in the preantibiotic era. Tympanocentesis is making a resurgence. It should be considered when a patient presents to the Emergency Department seeking treatment for a painful AOM.¹ The American Academy of Family Physicians, American Academy of Pediatrics, and the Centers for Disease Control and Prevention all include tympanocentesis

patients with an AOM and an immunodeficiency as they will often require directed therapy. Patients who develop AOM while taking appropriate antimicrobial therapy should undergo tympanocentesis to be evaluated for the organism responsible and its sensitivity to antibiotics. Tympanocentesis is performed when the patient has an AOM associated with unusually severe pain, signs of toxicity, or bullous myringitis. Tympanocentesis will provide immediate relief of pain, pressure, and/or hearing loss associated with AOM or a middle ear effusion. It may be performed in a patient with AOM and multiple antibiotic allergies to determine appropriate antibiotic selection. A tympanocentesis can be performed in the patient with AOM prior to the 48-hour “watchful waiting” period to allow accurate antibiotic selection if the patient is still symptomatic after 48 hours.

CONTRAINDICATIONS

There are no absolute contraindications to tympanocentesis. It should not be performed in a patient who is uncooperative and cannot be restrained and/or sedated as secondary injury may result. Uncooperative patients will require sedation to perform this procedure. **Tympanocentesis should be performed by an Otolaryngologist if the landmarks on the tympanic membrane are unable to be absolutely identified or are obscured.** Consult an Otolaryngologist prior to performing a tympanocentesis if an AOM is associated with anticoagulation, blood dyscrasias, a brain abscess, cochlear or other implant, dural sinus thrombosis, encephalitis, facial nerve palsy, intratympanic tumors, mastoiditis, meningitis, or stenosis of the external auditory canal. Do not perform a tympanocentesis if the patient has otitis externa.

EQUIPMENT

- Povidone iodine solution
- Topical otic anesthetic solution
- 21 gauge spinal needle, 2.5 or 3 inches long
- 3 mL aspirating syringe
- Ear speculum
- Ear wax curette
- Culture swabs and media
- Laboratory tubes for fluid cell count and differential
- Intravenous extension tubing
- Otoscope
- Headlamp or overhead surgical light source
- Frazier suction catheters
- Suction tubing
- Suction source
- CDT Speculum, optional

The Channel Directed Tympanocentesis or CDT Speculum (Walls Precision Instruments LLC, Baker City, OR) is a single patient use, disposable, easy to use, and sterile device with built-in safety features. It was designed for use by Primary Care Physicians in the outpatient setting. The CDT Speculum attaches to most commonly available otoscopes (**Figures 199-2 and 199-3**). The device allows tympanocentesis and the aspiration of middle ear effusions.

FIGURE 199-2. The CDT Speculum attached to an otoscope. **A.** Artist illustration. **B.** Photograph. (Photos courtesy of Walls Precision Instruments LLC.)

FIGURE 199-3. Proper grasping of the CDT Speculum attached to an otoscope. Note that the dominant thumb is placed on the actuator. (Photo courtesy of Walls Precision Instruments LLC.)

There are several advantages to the CDT Speculum over the traditional spinal needle on a syringe. The ensheathed needle protects the Emergency Physician as well as the patient from accidental needlesticks. The needle is incorporated into a speculum to prevent it from contacting the external auditory canal. The needle is automatically retracted by a spring into a protected position when not being used. A safety latch prevents accidental needle extension. Needle extension is limited and prevents it from being inserted too far into the middle ear cavity.

Some form of light is needed. One device is the Bionix Lighted Placement Tool (Bionix, Toledo, OH). The device is single use, disposable, and cost effective (**Figure 199-4**). Many Emergency Departments may have this device for cerumen removal. Other options include a headlight or overhead light. The use of an overhead light is the least favored option. It needs to be constantly moved, the Emergency Physician's head gets in the way, and it can cast shadows of items in the path of the beam.

PATIENT PREPARATION

Explain the risks, benefits, and alternative procedures to the patient and/or their representative. The postprocedural care should also be discussed. Obtain an informed consent for the procedure and place this in the medical record. When performing the procedure on a neonate or child, it is advisable to give the parent the option to leave the room or look away as the procedure can be disconcerting to some parents.

Clean and prepare the ear and external auditory canal. Place the patient supine on a locked gurney. View the tympanic membrane with an otoscope. Remove any cerumen from the external auditory canal using a curette (Chapter 198). The cerumen may also be flushed from the external auditory canal. The patient may need analgesia before cerumen removal if they are significantly tender. View the tympanic membrane again with the otoscope. Make sure the external auditory canal is clear. Apply povidone iodine solution to the external auditory canal for 2 to 3 minutes while it dries. Copiously irrigate the external auditory canal with sterile normal saline to remove all the povidone iodine.⁸

Administer analgesic medicine in advance of the procedure. Topical anesthetic solutions include benzocaine-antipyrine (e.g., Auralgan), viscous 4% lidocaine, 8% tetracaine, and cocaine. The administration of topical or local anesthesia is often not helpful in the presence of an acute infection. Topical anesthetics can potentially affect culture results due to their antimicrobial activity. If

A

B

FIGURE 199-4. The Bionix Lighted Placement Tool. **A.** The tool. **B.** The tool in use. (Photos courtesy of Bionix.)

culture results are not a concern, apply a topical anesthetic solution into the external auditory canal followed by a cotton ball. Allow the solution to remain for 5 to 10 minutes. Use a wick to absorb the topical anesthetic solution and dry the external auditory canal.⁸ Refer to Chapter 159 for performing a regional block of the ear and external auditory canal as an alternative to topical anesthesia.

Children and uncooperative patients must be restrained and/or sedated so that their head is immobile. A papoose board is effective for young children. Some practitioners use intravenous sedation. Only rarely is procedural sedation (Chapter 159) or general anesthesia required.

TECHNIQUES

TRADITIONAL NEEDLE-BASED TECHNIQUE

Bend a 21 gauge spinal needle at the hub to approximately 60°. Attach the spinal needle to a 3 mL aspirating syringe. Insert the ear speculum into the external auditory canal (**Figure 199-1A**). View the tympanic membrane through the ear speculum using a headlight or an overhead surgical light source for illumination.

Insert the spinal needle through the speculum. Advance the needle and penetrate just into the inferior half of the tympanic membrane (**Figures 199-1A and 199-1B**). **Avoid inserting the needle through the posterior superior quadrant of the tympanic membrane. This location is near the ossicles. Any movement of the**

needle near the ossicles could result in disarticulation of the ossicles requiring surgical repair. Aspirate the middle ear fluid into the syringe (Figure 199-1A). Simultaneously withdraw the syringe and ear speculum.

CHANNEL DIRECTED TYMPANOCENTESIS (CDT) SPECULUM

Remove the sterile CDT Speculum from the package. Attach the aspirator bulb and tubing to the CDT Speculum. Attach the CDT Speculum to the otoscope (Figures 199-2 and 199-3). Align the arm of the CDT Speculum with the insufflator port of the side of the otoscope head. Firmly attach the CDT Speculum onto the otoscope. Rotate the CDT Speculum 90° clockwise so that the arm is aligned with the seam on the top of the otoscope head. Disengage the safety latch.

Grasp the CDT Speculum with the dominant hand while simultaneously holding the otoscope and aspiration bulb with the non-dominant hand (Figure 199-3). Compress the aspirator bulb. Insert the CDT Speculum into the external auditory canal. Visualize the tympanic membrane through the CDT Speculum. Look through the CDT Speculum. Press the actuator with the dominant thumb to extend the needle toward the inferior portion of the tympanic membrane (Figure 199-3). Continue to press the actuator to keep advancing the needle through the tympanic membrane and no more than 1 to 2 mm into the middle ear cavity. Release the compression on the aspirator bulb to aspirate the middle ear fluid. Release the pressure on the actuator to retract the needle. Withdraw the CDT Speculum from the external auditory canal.

Place the tip of the CDT Speculum over the culture swab or medium. Compress the aspirator bulb to expel the middle ear fluid sample. Discard the CDT Speculum.

ALTERNATIVE TECHNIQUE

An alternative method involves attaching intravenous extension tubing between the spinal needle and the syringe. The Emergency Physician can observe the tympanic membrane, insert the spinal needle, and leave a hand available for manipulation of the ear speculum or a suction catheter. An assistant is required to hold the syringe and aspirate the middle ear fluid. The remainder of the technique is as described previously.

ASSESSMENT

Tympanocentesis will decompress the middle ear pressure and provide the patient significant symptom relief. Transfer the fluid into appropriate laboratory medium and containers as quickly as possible. Label the containers and have them transported to the laboratory for a Gram's stain, culture and sensitivities, cell count, and differential of the cells present.

AFTERCARE

Most of the distress associated with the procedure in small children is due to immobilization. Immediately release the child from the papoose or restraining device. Most patients will have immediate improvement in their pain and their hearing. Some Otolaryngologists will rinse the external auditory canal after a tympanocentesis with a 3% peroxide solution and then absorb the solution with a wick. This is optional and at the discretion of the treating Emergency Physician. The small opening in the tympanic membrane may drain (i.e., blood and middle ear fluid) for 48 to 72 hours. Instruct the patient and/or their caregivers to keep the ear dry for 2 to 3 days. This is especially true during bathing or hair washing. A cotton earplug coated with a thin

film of petroleum jelly (e.g., Vaseline) works well. The tympanic membrane usually spontaneously heals within 48 to 72 hours but can take up to 10 days. Follow-up for laboratory results and documentation of antimicrobial change or appropriateness is necessary in 48 to 72 hours.

COMPLICATIONS

Complications are uncommon. The most frequently cited complications include laceration of the ear canal, persistentTM perforation with or without otorrhea, development of a scar on the tympanic membrane, and otitis externa. Pain and bleeding are usually minimal and self-limited. One of the most significant and rare complication is the disruption of the ossicles of the middle ear. **Disruption of the ossicles can be avoided by inserting the needles into the inferior half of the tympanic membrane and preventing patient movement during the procedure.** Injury to the chorda tympani, facial nerve, or internal carotid artery is theoretically possible but virtually unheard of with this procedure.

SUMMARY

Acute otitis media is a common infection of childhood but is also seen in adults. Most episodes respond quickly, with or without antimicrobial therapy. Tympanocentesis can be used to direct antimicrobial therapy in patients when a clinical response is delayed, host immunosuppression exists, or unusual organisms are suspected. Tympanocentesis can be used to provide immediate pain relief from a severe middle earache. The procedure is quick and simple to perform in the Emergency Department.

Auricular Hematoma Evacuation

Eric F. Reichman

INTRODUCTION

Blunt trauma to the auricle can cause abrasions, ecchymosis, hematoma formation, and lacerations. Abrasions and ecchymosis of the auricle require no therapy other than oral analgesics and observation for infection.¹ Some authors recommend the application of topical antibiotics to all abrasions as prophylaxis for infection.²

Lacerations to the auricle are addressed in Chapter 119. This chapter addresses the management of an auricular hematoma.

Injuries to the auricle are common due to its exposed position and lack of protection from surrounding structures.³ The most common cause for an auricular hematoma formation is blunt trauma while participating in the contact sports of wrestling or boxing.^{1,2,4-6} Such trauma may occur in other situations including assaults, falls, fights, and motor vehicle crashes. Auricular trauma and hematomas are common in children due to the high incidence of head injuries during playtime.^{2,4} Blood dyscrasias may also cause an auricular hematoma.

An auricular hematoma presents as a firm and painful swelling that obscures the normal convolutions on the lateral aspect of the auricle. It can develop within minutes to hours of the blunt trauma. **An auricular hematoma must be evacuated to prevent the cosmetic disfigurement known as cauliflower ear.**⁷ The sooner it is evacuated, the less chance of permanent disfigurement.^{4,5} After evacuation, the patient requires a pressure dressing to the auricle, oral antibiotics, and close follow-up to prevent complications.^{2,5,8,9}

ANATOMY AND PATHOPHYSIOLOGY

The auricle is that portion of the external ear that projects from the side of the head. It functions to augment sound delivery to the tympanic membrane and assist in sound localization. It is fixed in position by both ligaments and muscles.¹⁰ It has an underlying cartilaginous framework that is 0.5 to 1.0 mm thick and provides the auricle with its unique shape. The cartilage is a single, thin sheet of flexible yellow elastic cartilage with many convolutions on the lateral surface.¹¹ The only portion of the auricle without cartilage is the lobule in which fibrofatty tissue replaces the cartilage.¹⁰ **The cartilage is avascular and derives its blood supply and nutrients from the adjacent perichondrium.**¹²

The skin covering the auricle is similar to that elsewhere on the body.¹³ It contains sebaceous glands and a varying number of hair follicles. The skin on the lateral surface of the auricle is tightly adherent to the perichondrium and lacks a subcutaneous layer (Figure 200-1). The skin on the medial surface of the auricle is loosely attached and has a layer of subcuticular tissue between the skin and perichondrium.

FIGURE 200-1. Cross-section of the auricle. The skin on the medial surface has a layer of loose connective tissue that is lacking on the lateral surface.

A

B

FIGURE 200-2. An auricular hematoma. **A.** The blood collects between the perichondrium and the cartilage. **B.** Photograph of a patient. (Used with permission from Knoop KJ, Stack LB, Storrow AB, Thurman RJ (eds): *The Atlas of Emergency Medicine*, 3rd ed. New York: McGraw-Hill; 2010. Photo contributor: C. Bruce MacDonald, MD.)

Trauma may cause the perichondrium to be torn off the underlying cartilage due to the tight attachment of the skin to the perichondrium on the lateral surface of the auricle. This traumatic avulsion of the perichondrium causes hemorrhage into the space between it and the cartilage allowing a hematoma to form (Figure 200-2). Bleeding into this potential subperichondral space causes dissection of the perichondrium from the underlying cartilage. Auricular hematomas can be painful due to the rich sensory innervation to the area and the accumulation of blood in this relatively closed space.¹² **Failure to adequately evacuate a hematoma may lead to cartilage necrosis and a deformed ear (Figure 200-3).**^{7,14,15} The necrosis is due to a combination of separating the cartilage from its blood supply and direct pressure effects from the hematoma.

The cauliflower ear is a purely cosmetic deformity that results from an auricular hematoma not being evacuated and allowing the auricle to spontaneously heal. The hematoma is invaded by fibroblasts and slowly replaced by fibrous tissue. This organization of the hematoma causes irregular thickening of the auricle. The perichondrium, elevated from the cartilage by the hematoma, senses the lack of adjacent cartilage and activates chondroblasts. New cartilage is deposited on the surface of the hematoma causing further thickening and deformity of the auricle.

FIGURE 200-3. An undrained auricular hematoma results in a cauliflower ear. (Used with permission from Knoop KJ, Stack LB, Storrow AB, Thurman RJ (eds): *The Atlas of Emergency Medicine*, 3rd ed. New York: McGraw-Hill; 2010. Photo contributor: C. Bruce MacDonald, MD.)

INNERVATION OF THE AURICLE

A brief review of the innervation of the auricle will later aid in understanding the technique of regional anesthesia. Three nerves contribute to the sensory enervation of the auricle (**Figure 200-4**).^{9,12,13,16-18} The auriculotemporal branch of the mandibular division of the trigeminal nerve supplies sensation to the upper, lateral surface of the auricle. This nerve emerges subcutaneously just anterior to the auricle at the level of the external auditory canal. Two branches of the cervical plexus become subcutaneous at the posterior border of the midportion of the sternocleidomastoid muscle and ascend to the auricle. The lesser occipital nerve provides sensory innervation to the upper medial surface of the auricle and middle of the lateral auricular surface. The great auricular nerve provides sensory

innervation to most of the medial surface and the lower half of the lateral auricular surface.

INDICATIONS

An auricular hematoma must be evacuated. The indication for evacuation is to prevent the cosmetic deformity known as the cauliflower ear (**Figure 200-3**).⁸ It is preferable to evacuate the hematoma within 12 to 24 hours after its occurrence. Although there is no urgency to immediately evacuate the hematoma, the longer it remains, the higher the chance of clot organization and new cartilage deposition.^{8,19}

CONTRAINDICATIONS

There are no absolute contraindications to the evacuation of an auricular hematoma. If the skin overlying the hematoma is cellulitic or if purulent material is drained from the hematoma, the patient will require hospital admission and intravenous antibiotics.^{1,9} An Otolaryngologist or Plastic Surgeon should be immediately consulted on these patients. The auricular hematoma should be evacuated by a consultant if it has been present for more than 5 to 7 days. These hematomas have already begun organization and new cartilage has developed requiring curettage associated with the evacuation.^{8,19-21} An uncooperative patient (e.g., a young child or due to altered mental status) may require evacuation under procedural sedation or in the Operating Room.

EQUIPMENT

■ AURICULAR ANESTHESIA

- Povidone iodine or chlorhexidine solution
- 1 mL syringe
- 10 mL syringe
- 25 to 30 gauge needles, 2 inches long
- 10 to 20 mL of local anesthetic solution without epinephrine

FIGURE 200-4. The sensory innervation of the auricle. **A.** The distribution of cutaneous nerves surrounding the auricle. **B.** An enlarged view of the auricle demonstrating the cutaneous innervation.

■ AURICULAR HEMATOMA ASPIRATION

- Povidone iodine or chlorhexidine solution
- Tuberculin or insulin syringe
- 0.25 mL of local anesthetic solution without epinephrine
- 10 mL syringe
- 18 gauge needle
- Topical antibiotic ointment

■ AURICULAR HEMATOMA INCISION AND DRAINAGE

- Auricular anesthesia as above
- #15 surgical scalpel blade on a handle
- Curved hemostat
- Sterile drain (optional)
- 10 mL syringe
- 18 gauge angiocatheter without the needle
- Sterile saline
- Topical antibiotic ointment
- Forceps

■ MASTOID PRESSURE DRESSING

- Petrolatum gauze
- Cotton balls soaked in sterile saline
- Dry cotton balls
- 4×4 gauze squares
- 4 inch elastic bandage
- Scissors

■ SURGICAL PRESSURE DRESSING

- Cotton bolsters or dental rolls
- Needle driver
- 4–0 monofilament nylon suture

PATIENT PREPARATION

Explain the risks, benefits, and potential complications of the procedure to the patient and/or their representative. The postprocedural care should also be discussed. Obtain a signed consent for the procedure. Some Emergency Physicians omit the signed consent and place the following statement in the procedure note: “The risks, benefits, and complications were described and discussed with the patient. They understood this and gave verbal consent for the procedure.” This decision must be based on physician preference, hospital guidelines, and state guidelines for documentation requirements.

Remove any dirt and debris from the auricle and surrounding skin. Apply povidone iodine or chlorhexidine solution to the same areas. Follow aseptic technique for the remainder of the procedure.⁴ In patients who are anxious and without other associated injuries, the administration of intramuscular, intravenous, or oral lorazepam (Ativan) or diazepam (Valium) may be beneficial.¹⁸ Most patients do not need procedural sedation and analgesia.

AURICULAR ANESTHESIA

The local anesthetic solution used for auricular anesthesia should contain no epinephrine.^{2,16,17,22} Epinephrine is not used for fear of intense vasoconstriction of end arterioles resulting in decreased

perfusion with possible ischemia and necrosis of the auricle. Some authors recommend the use of 1/100,000 epinephrine mixed with the local anesthetic solution.^{1,18,19} The epinephrine may decrease bleeding by its vasoconstrictive action. It may also prevent reaccumulation of the hematoma after it has been evacuated. Authors who advocate using epinephrine state that the auricle has a rich blood supply and that, based on anecdotal evidence, there is no danger of ischemia or necrosis from the use of epinephrine in healthy patients without evidence of traumatized vascularity. **Although many physicians will use epinephrine, it has not been proven safe to use or proven to prevent reaccumulation of the hematoma.** It may be wiser to be conservative and not use epinephrine than to use it and have to deal with the complications to the patient and potential litigation.

The choice of which local anesthetic to use is physician-dependent. Lidocaine (1%) is the most commonly used local anesthetic. Long-acting local anesthetic solutions, such as bupivacaine (Marcaine) or etidocaine (Duranest), may be used to provide analgesia for several hours after the procedure is completed.¹⁷

The methods of anesthesia for evacuation of an auricular hematoma range from none to a superficial skin wheal to a regional block. Some authors advocate using no anesthesia if needle aspiration of a small and fresh hematoma is performed.² This is not generally recommended as the pain from an 18 gauge needle aspiration is more uncomfortable than local anesthesia infiltration.

If using the aspiration technique to evacuate the hematoma, local anesthetic solution can be infiltrated directly over the hematoma. Apply a 25 to 30 gauge needle on a 1 mL syringe. Place a skin wheal using 0.25 mL of local anesthetic solution without epinephrine over the hematoma in the area of maximum fluctuance. **When placing the skin wheal be careful not to inject the local anesthetic solution into the hematoma.** This will cause expansion of the hematoma and increase the separation of the perichondrium from the underlying cartilage.²² It may also cause new bleeding, which can increase the possibility of hematoma reaccumulation.

A regional auricular block is the preferred method to obtain anesthesia.¹⁶ It prevents distortion of the auricle from direct injection and further separation of the perichondrium from the underlying auricular cartilage.²² Subcutaneous infiltration of the surrounding skin is less painful than injection directly into the sensitive auricular skin.¹⁸ The landmarks for regional anesthesia are simple to locate, consistent, and predictable. The greatest reason for failure of an auricular block is incorrect needle placement.¹⁷ A regional auricular block can be done prior to using the aspiration technique or the incision and drainage technique to evacuate the hematoma. If the aspiration technique fails (i.e., hematoma reaccumulates), then there is no need to reprep and perform an auricular block prior to performing the incision and drainage.

There are three methods to perform a regional auricular block (**Figures 200-5 and 200-6**). Each method blocks the lesser occipital, great auricular, and auriculotemporal nerves. Some Emergency Physicians prefer to subcutaneously inject local anesthetic solution circumferentially around the attachment of the auricle to the head (**Figure 200-5**).^{2,12,16,22} An alternative method is based on blocking the sensory supply to the ear in a more anatomic distribution (**Figure 200-6**).^{9,17} This latter method uses half the anesthetic and half the number of subcutaneous injections than the former method. For these reasons, this author prefers the second method which is described in the following paragraph.

To perform a regional auricular block, first cleanse the auricle and surrounding skin of any dirt and debris. Apply povidone iodine or chlorhexidine solution. Place a skin wheal of local anesthetic solution 0.5 cm below the pinna of the auricle (**Figure 200-6A**). Insert

FIGURE 200-5. Regional anesthesia of the auricle. The technique of circumferential application of local anesthetic solution. Shaded areas represent subcutaneous infiltration of local anesthetic solution.

a 2 inch, 25 or 27 gauge needle through the skin wheal aimed just posterior to the attachment of the auricle to the head. Infiltrate subcutaneously, in a superior direction, always remaining 0.5 to 1.0 cm posterior to the auricular attachment to the head. Stop infiltrating at the level of the superior attachment of the auricle to the head. This infiltration requires 4 to 7 mL of local anesthetic solution. Withdraw the needle almost completely. Redirect the needle through the skin wheal and aimed just anterior to the attachment of the auricle to the head. Infiltrate subcutaneously, in a superior direction, always remaining 0.5 to 1.0 cm anterior to the auricular attachment to the head. Stop infiltrating at the level of the superior attachment of the auricle to the head. This infiltration also requires 4 to 7 mL of local anesthetic solution. **Care must be taken not to inject too deeply anterior to the auricle as it can cause temporary paralysis of the facial nerve.** An alternative to the anterior infiltration is the injection of 3 to 4 mL of local anesthetic solution just superior and anterior to the tragus (**Figure 200-6B**).^{1,23} This injection blocks the auriculotemporal nerve at its origin. **Allow 10 to 15 minutes for the full anesthetic effect prior to beginning the procedure.**²²

TECHNIQUES

The methods for treating and managing an auricular hematoma require the evacuation of the hematoma and replacing the perichondrium onto the underlying cartilage. The techniques include aspiration, incision and drainage, and closed suction drainage.

FIGURE 200-7. The aspiration of an auricular hematoma. The hematoma is expressed with the thumb and index finger as negative pressure is applied to the syringe.

The first two techniques will be described in detail. The closed suction technique requires inpatient admission and is not a procedure to be performed in the Emergency Department. It will therefore not be described here.

ASPIRATION

Some consider the aspiration technique to be the primary method to evacuate an auricular hematoma.^{2,3,5,6,24} They reserve the incision and drainage technique for incomplete aspiration or recurrence of the hematoma. Unfortunately, the hematoma frequently recurs after using the aspiration technique and the patient requires a second procedure to evacuate the hematoma.^{1,3,6,25} Because of the high rate of recurrence, this author and others prefer to use the incision and drainage technique as the primary procedure.¹⁹

Clean and prep the skin. Anesthesia is achieved by performing a regional auricular block or by placing a skin wheal of local anesthetic over the hematoma. Attach an 18 gauge needle onto a 10 mL syringe. Insert the needle into the area of maximum fluctuance (**Figure 200-7**). Apply negative pressure to the syringe by withdrawing the plunger to evacuate the hematoma. Express or “milk” the hematoma between the thumb and index finger of the nondominant hand while applying negative pressure with the syringe to ensure complete evacuation of the hematoma (**Figure 200-7**).

Remove the needle and apply manual pressure to the area of the former hematoma for 3 to 5 minutes. If the hematoma recurs or if complete aspiration is not possible, perform the incision and drainage technique. If the hematoma is completely evacuated and does not recur, apply topical antibiotic ointment and a pressure dressing.

FIGURE 200-6. Regional anesthesia of the auricle. **A.** A more anatomic auricular block. **B.** An alternative regional block that anesthetizes the auriculotemporal nerve at its origin. Local anesthetic solution is injected at the ⊗ symbol. Shaded areas represent subcutaneous infiltration of local anesthetic solution.

There are several disadvantages to this technique. First, the hematoma frequently recurs.^{1,3,6,25} This means that the patient often needs a second drainage procedure. Even if the hematoma is adequately evacuated, the elimination of the dead space is problematic.²⁵ The dead space may fill with blood or serous fluid requiring a second procedure. A surgically applied pressure dressing may alleviate the dead space and make the aspiration technique more successful. Finally, the aspiration technique may not remove all of the hematoma.¹ Again, the patient will need a second procedure. For these above stated reasons, the aspiration technique is not the preferred method to drain an auricular hematoma.

A modification of this technique aspirates the hematoma with an angiocatheter.²⁶ Aspirate the hematoma with a 27 gauge angiocatheter. Leave the catheter in place while removing the needle. Carefully cut off the hub from the catheter. The catheter is left in place like a drain. Apply a dressing. This was a small study using only 53 patients. In six patients (11%), the catheter fell out within 72 hours allowing the hematoma to reaccumulate in three of the patients (6%). They repeated the procedure in these three patients. The auricle healed without complications in all the patients.

INCISION AND DRAINAGE

This is the preferred technique to evacuate an auricular hematoma.¹⁹ It requires a regional auricular block for anesthesia. This technique takes more time to perform than the aspiration technique.

As noted previously, the skin should be cleaned and prepped in the usual manner. Perform a regional auricular block to provide adequate analgesia. Allow the block 10 to 15 minutes to achieve maximal effect.²² Incise the auricular skin with a #15 surgical scalpel blade at the edge of the hematoma (**Figure 200-8A**). **When making the incision, it should follow the curvature of the pinna and be no longer than 1 cm.** Gently peel this skin and attached perichondrium off the hematoma using forceps. Express or “milk” the hematoma with the thumb and index finger of the nondominant hand. Insert a curved hemostat and gently loosen any remaining blood clot (**Figure 200-8B**). Fill a 10 mL syringe with sterile saline and attach a plastic 18 gauge angiocatheter. Gently flush out the area of the hematoma (**Figure 200-8C**).

Reapproximate the skin and perichondrium on the cartilage. Compress the tissue to eliminate any fluid and dead space. Some authors apply a small rubber drain through the incision to prevent accumulation of blood or serous fluid.^{4,9,27} The use of a drain is optional. A drain can be made by cutting a small strip from a sterile Penrose drain.

Apply manual pressure to the area of the former hematoma for 3 to 5 minutes. If the hematoma or serous fluid does not reaccumulate, apply topical antibiotic ointment and a pressure dressing as described below. If the hematoma or serous fluid does reaccumulate, consider inserting a rubber drain or applying a surgical pressure dressing.

PRESSURE DRESSINGS

A pressure dressing must be applied to the auricle after the successful drainage of an auricular hematoma. It prevents reaccumulation of the hematoma or serous fluid and supports the auricle while the perichondrium reattaches to the cartilage.^{3,6,11} The pressure dressing must be applied for at least 48 hours.⁴ The pressure dressing can be the traditional mastoid dressing or a surgically applied dressing.^{19,22,25,28} **These pressure dressings apply even pressure over the entire auricle without compromising the blood flow while simultaneously eliminating the dead space within the wound.**²²

MASTOID PRESSURE DRESSING

The most commonly applied dressing is the mastoid pressure dressing (**Figure 200-9**).²⁹ Although simple to place, it has many disadvantages when compared to the surgically applied pressure dressing. It is bulky and hard to keep in place. It is very conspicuous. Patients must keep it dry and remain relatively inactive to prevent it from coming off.

Place a piece of sterile dry cotton in the external auditory canal and level with the base of the auricular cartilage. Mold a sterile material that conforms easily onto all the convolutions of the auricle until it is level with the lateral helical rim (**Figure 200-9A**). The choices of material include cotton balls soaked in mineral oil, cotton balls soaked in saline, or petrolatum gauze. The material chosen is left to Emergency Physician preference and what is available in the Emergency Department. This author prefers to use petrolatum gauze. The petrolatum gauze allows the dressing to be removed with minimal trauma to the ear. Pack the auricle with saline-soaked cotton balls. **All the convolutions of the auricle must be thoroughly packed. The packing of the auricular convolutions assures even application of pressure to all portions of the auricle.**

Cut out and discard a semicircle or a V-shaped section from a pile of gauze squares. Place the remaining C-shaped gauze pads behind the auricle (**Figure 200-9B**). The gauze pads should be built up

FIGURE 200-8. Incision and drainage of an auricular hematoma. **A.** An incision is made along the helical rim. **B.** The hematoma is evacuated with the aid of a hemostat. The thumb and index finger express the hematoma from the subperichondral space. **C.** The subperichondral pocket is flushed with normal saline to remove any residual blood and clot.

FIGURE 200-9. The traditional mastoid dressing. The convolutions are covered with a layer of petroleum gauze. **A.** Saline-soaked cotton balls are packed over the convolutions, level with the helical rim. **B.** Trimmed gauze squares are placed between the auricle and the head. **C.** Fluffed gauze is placed over the auricle. **D.** The circumferential application of an elastic gauze bandage to the head. The bandage should cover the injured auricle and not the contralateral auricle.

until they completely fill the area between the auricle and the head. This padding is used to support the auricle as well as prevent undue contortion or uneven pressure on the auricle from the compression dressing.²

Unfold and fluff several gauze squares or open a roll of gauze. Place the fluffed gauze over the lateral surface of the auricle (**Figure 200-9C**). Wrap an elastic bandage snugly over the auricle and around the head to hold the dressing in place (**Figure 200-9D**). **The circumferential head dressing should not encompass the opposite auricle.** The elastic bandage is used to compress the auricle between the two layers of gauze padding.

SURGICAL PRESSURE DRESSING

A surgically applied pressure dressing may be used instead of the traditional mastoid dressing (**Figure 200-10**).^{1,8,19,25} This dressing applies even pressure over the former hematoma site to prevent reaccumulation. It takes more skill to apply than the traditional mastoid dressing. Aseptic technique is mandatory to prevent infection and perichondritis. This dressing requires a skin prep of a much

wider area to include the entire medial and lateral surface of the ear and the surrounding skin.

The surgically applied pressure dressing has many advantages over the traditional mastoid dressing. It produces pressure exactly where it is needed. The wound is not obscured with a bulky dressing. This allows the patient to easily observe and monitor the site for reaccumulation of fluid and possible infection. This dressing is comfortable and well tolerated by the patient. It is unlike the bulky and conspicuous mastoid dressing that is difficult to keep in place, especially when sleeping. The dressing can remain in place while monitoring the auricle unlike the mastoid dressing that must be removed and replaced daily. The patient can remain active, including taking a shower, without fear of the dressing coming undone. The surgical pressure dressing is adaptable to any location or a variety of hematomas.

Trim a cotton dental bolster or cotton roll to fit the convolution of the auricle over the site of the drained hematoma. Place the cotton roll over the site of the former hematoma (**Figure 200-10A**). Place a second dental roll on the medial surface of the auricle opposite the first dental roll (**Figures 200-10A and 200-10B**). Place the needle of a 4-0 monofilament nylon suture immediately adjacent to the first cotton bolster. Pass the suture through the entire thickness of the auricle and out the medial surface. Pass the needle over the second cotton bolster and back through the auricle. Snugly tie the suture over the anterior cotton bolster (**Figure 200-10B**). The suture should be snug enough to allow the cotton bolsters to firmly hold the perichondrium to the cartilage without causing vascular compromise. Apply additional sutures using the same technique until the cotton bolsters are firmly attached and any dead space is eliminated. Depending upon the location of the hematoma, it may require a minimum of two to a maximum of four bolsters to reapproximate the skin and perichondrium and to eliminate all of the dead space.

Monofilament nylon is the preferred suture material for this procedure.⁸ It causes less tissue reaction than silk, cotton, gut, or absorbable sutures. It has less of a tendency to cut the ear tissues when tied over the cotton bolsters. Monofilament nylon is less likely to wick bacteria into the auricle and cause an infection than multifilament nylon. The suture may be safely left in place for up to 3 weeks without any complications.

ALTERNATIVE TECHNIQUES

An alternative to packing the pinna with petrolatum gauze is to use either ENT silicone putty or dental impression material.^{30,31} Evacuate the hematoma as described previously. Mix the chosen material

FIGURE 200-10. A surgically applied pressure bandage. **A.** A cotton roll is applied to the lateral surface of the auricle over the site of the evacuated hematoma. A second cotton roll is applied on the medial surface of the auricle directly beneath the first cotton roll. The cotton rolls are secured with 4-0 monofilament nylon suture. **B.** Cross-sectional illustration of the surgical pressure dressing. The position of the cotton rolls and suture is seen in relation to the incision site. Note that the perichondrium is apposed to the cartilage and the dead space is eliminated.

to form a uniform composite and activate it. Mold it to fill the pinna, wrapping over the pinna and filling the space between the medial surface of the ear and the head. The putty or impression material will solidify in a few minutes after mixing it and the application. Apply an elastic bandage as described previously. Unfortunately, ENT silicone putty and dental impression material are not often available in the Emergency Department.

The placement of cotton bolsters is often cumbersome and difficult if the Emergency Physician has little experience with this technique. An alternative is to use thermoplastic splinting material.³² Trim a sheet of thermoplastic splinting material to form a lateral and medial splint of an appropriate size to conform to the lateral and medial surfaces of the ear, respectively. Place the splints in warm water to soften them. Apply the splints to the surfaces of the ear, mold them to the contours of the ear, and apply pressure until they cool and become rigid again. Suture the rigid splints through the ear as described previously.

A second surgical alternative to the use of bolsters is to apply running mattress sutures through the ear to reapproximate the skin and perichondrium.³³⁻³⁸ Begin posteriorly and weave 4-0 Vicryl or chromic gut suture through-and-through the ear in a running pattern to reapproximate the soft tissues and repair the ear contours. The main advantages of this technique include eliminating bolsters, eliminating the bulky dressing, and the comparable success rates while minimizing the reaccumulation of blood or fluid.

A promising technique involves the injection of OK-432 into the hematoma.³⁹ This agent was first developed as an immunotherapy for cancer. The advantages of OK-432 injection are that it is simple, is easy to accomplish, and avoids an incision and drainage. There is not enough information to recommend this technique at this time.

Another small study injected fibrin glue after the incision and drainage procedure.⁴⁰ This was followed by suture-secured dental bolsters. This seemed to work, allowing healing with no complications. There is not enough information to recommend this technique at this time.

AFTERCARE

The postprocedural care of the auricle is as important as the initial hematoma evacuation. Proper follow-up and care can minimize or prevent any cosmetic deformities. All patients should be seen within 12 to 24 hours to reevaluate the auricle for infection or reaccumulation of the hematoma or serous fluid. Analgesia can be provided by the use of nonsteroidal anti-inflammatory agents. Determine the patient's tetanus immune status and provide prophylaxis as required.

Provide all patients with oral and written instructions regarding the signs and symptoms of cellulitis and perichondritis. This includes the immediate return to the Emergency Department for increasing pain, progressive swelling, redness, tenderness, and warmth. Prophylaxis with oral antibiotics is indicated with any laceration, incision, or puncture of the auricular skin.⁴ Prescribe antibiotics for 5 days.^{4,5,19} Recommendations include a range of first-generation cephalosporins, antistaphylococcal antibiotics, or antipseudomonal antibiotics.^{4,5,19}

Apply the pressure dressing for a minimum of 48 hours.⁴ A pressure dressing is recommended for a total of 4 to 5 days. A mastoid dressing must be removed daily to evaluate the auricle and then reapplied. A surgically applied dressing will avoid daily visits to the physician.

Drain any residual clot or serous fluid at the follow-up visit. This can easily be accomplished by needle aspiration and replacement of the pressure dressing.^{6,28} If necessary, a sterile drain can be inserted.⁹ All drains must be removed within 48 hours of placement to decrease the risk of infection.

COMPLICATIONS

The complications are primarily related to incomplete evacuation of the hematoma or reaccumulation of the hematoma. Incomplete evacuation of the hematoma, if by the aspiration technique, requires an incision and drainage of the hematoma. If necessary, gentle curettage of the cartilage with a hemostat should dislodge the clot. Reaccumulation of the hematoma or serous fluid must be evacuated. Consider placing a sterile drain into the incision.⁹ Another option is to place a surgical pressure dressing.⁸ A hematoma located within the cartilage will result in a treatment failure and require operative management.⁴¹

Infection may complicate any surgical procedure. This may be due to reaccumulation or incomplete evacuation of the hematoma which then becomes infected. Strict adherence to aseptic technique will usually prevent infection. Since patients are prophylactically placed on antibiotics, any cellulitis of the auricle at the follow-up visits requires hospital admission and intravenous antibiotics.

Perichondritis is the most feared complication. It is an aggressive and rapidly progressive infection. The auricle will become red, hot, and exquisitely tender if perichondritis develops. This is followed by diffuse swelling and abscess formation. This infection can lead to significant cartilage necrosis and a deformed ear if not promptly treated. *Pseudomonas aeruginosa* is isolated in 95% of patients with perichondritis.¹ Over 50% of cases are polymicrobial with *Staphylococcus aureus* associated with *Pseudomonas aeruginosa*. These patients require Otolaryngology or Plastic Surgery consults for surgical debridement, broad-spectrum intravenous antibiotics, and hospital admission.^{1,9}

SUMMARY

An auricular hematoma forms in minutes to hours after blunt trauma to the ear. It presents as a firm and painful swelling that obscures the normal convolutions on the lateral aspect of the auricle. It requires drainage to restore the normal convolutions of the auricle and prevent future deformity. Complete evacuation can be accomplished by needle aspiration or by incision and drainage. After the procedure, prescribe oral antibiotics prophylactically to prevent infection. Follow-up is required within 12 to 24 hours of the procedure to evaluate the patient for reaccumulation of the hematoma and infection. Patients should be educated about the signs and symptoms of perichondritis. Frequent wound evaluation is required until the auricle is healed.

Nasal Medication Administration

Crystal Ives Tallman and Joel Tallman

INTRODUCTION

The rapid administration of lifesaving medications in situations of overdose or epilepsy is of indisputable importance in the prehospital and Emergency Department (ED) settings. Decreasing the time to analgesia for children and adults with painful conditions is a clear priority and the intranasal administration of medications is ideal. It is an important tool for the Emergency Physician to have in their armamentarium. The intranasal administration of medications for anxiolysis in children and adults may limit the need for painful intravenous (IV) line insertion or intramuscular (IM) administration. The old method of dripping the medication from a syringe was not effective. Most of the medication ran into the nasopharynx, was swallowed, and resulted in erratic absorption. Atomizers are now inexpensive, single use, and available in many EDs.

ANATOMY AND PATHOPHYSIOLOGY

The normal physiologic function of the nasal cavities is to warm, humidify, and partially filter outside air. The qualities that make the nose effective physiologically also make it an ideal site for drug administration. The nose has a large surface area of approximately 160 cm² with a thin permeable barrier that is 2 to 4 mm thick and an extensive capillary network.¹ The blood flow to nasal mucosa per cubic centimeter of tissue is greater than brain, liver, or muscle tissue.² The large mucosal surface with its rich vascular bed provides for excellent absorption and drug bioavailability. Relatively lipid-soluble drugs are rapidly and reliably absorbed without the first-pass metabolism of taking medications orally.²

Atomized medication delivery improves bioavailability by increasing mucosal coverage and decreasing the amount of medication lost to swallowing. The maximum absorption is reported for doses of 0.15 mL per nostril.² The recommended maximum volume is less than 1 mL per nostril for adults and 0.3 mL per nostril for pediatric patients. Medication may need to be divided into multiple smaller doses to maximize efficacy and minimize patient discomfort. Using a more concentrated formulation of a medication may decrease the number of doses required. Using both nostrils improves absorption.³

INDICATIONS

The intranasal administration of medications is indicated for certain medications when rapid delivery is desired. It is also indicated for patients with limited or difficult vascular access. An additional benefit is the avoidance of painful IV line insertion attempts or IM injections. The advantages and disadvantages of intranasal medication are listed in **Table 201-1**. It can be used prior to many ED procedures (**Table 201-2**). The indications and dosing for medications commonly given by the intranasal route are listed in **Table 201-3**.¹⁻⁵⁴ The specific characteristics of each medication is noted in Chapter 12.

ANALGESIA

Intranasal fentanyl provides rapid onset of pain relief, results in minimal side effects, and decreases the time to analgesia.⁴⁻¹³

TABLE 201-1 The Advantages and Disadvantages of Intranasal Medication Administration

Advantages	Disadvantages
Avoids liver and gastrointestinal first-pass metabolism	Absorption inhibited by blood
Avoids needle anxiety	Absorption inhibited by secretions
Can administer with nausea and vomiting	Atomizer device not available
Fast onset	Chronic nasal conditions affect absorption
Inexpensive atomizers	Drip from a syringe not very effective
Minimal cooperation needed	Limited medications to be administered
Noninvasive	Nasal mucosa burning
No palatability issues	Nasal mucosa irritation
No possible needlesticks	
Plasma profile similar to IV route	
Premedicate special needs children	
Premedicate young children	

Intranasal fentanyl provides effective analgesia for adults and provides equivalent analgesia to IV morphine.^{5,14,15} Intranasal ketamine provides effective analgesia in children and adults but is associated with more minor side effects (e.g., dizziness and drowsiness).^{18–20} A diamorphine spray is available for nasal pain relief.²¹

ANXIOLYSIS

Intranasal midazolam is effective for anxiolysis and sedation in pediatric patients prior to painful procedures.^{22,23} Intranasal midazolam is frequently used in adults for preprocedural anxiolysis with good effects and reduces the need for IV lines. No cases of paradoxical reactions are documented in the literature from the use of intranasal midazolam. Intranasal dexmedetomidine is an effective agent for anxiolysis and sedation prior to procedures or imaging in children.^{24–27} It may be more effective than intranasal midazolam.^{24,25} Intranasal fentanyl can provide analgesia and sedation for children undergoing painful procedures.^{28,29}

OVERDOSE REVERSAL

The intranasal administration of reversal agents can be lifesaving when IV access is not available. Naloxone has been long established

TABLE 201-2 Some of Uses for the Administration of Nasal Medications

Abscess incision and drainage
Bite wound cleaning and repair
Burn wound care
Casting and splinting
Foreign body removal
Joint dislocation reduction
Laceration repair
Lumbar puncture
Nail bed repair
Paracentesis
Patients with nothing by mouth (NPO) status
Premedication prior to procedures
Procedures for special needs children
Procedures in young children
Radiologic imaging (e.g., computed tomography, magnetic resonance imaging, ultrasound)
Seizures
Sexual assault examinations
Status epilepticus
Thoracentesis

TABLE 201-3 Commonly used Intranasal Medications in Children and Adults

Medication	Indication and dosing	Comments
Fentanyl	Pain control: 1–2 µg/kg Sedation: 2–3 µg/kg	Time of onset: 5–10 minutes Duration of action: 30–120 minutes Concentration: 50–1000 µg/mL
Midazolam	Sedation: 0.3–0.5 mg/kg Seizure: 0.2–0.3 mg/kg	Time of onset: average of 5–10 minutes Duration of action: average of 40 minutes; ranges from 30–120 minutes Concentration: 5 mg/mL
Ketamine	Pain control: 0.5–1 mg/kg	Time of onset: 5–15 minutes Duration of action: 30–60 minutes Concentration: 50 mg/mL
Dexmedetomidine	Sedation: 2.5–3.5 µg/kg	Time of onset: average of 12 minutes Duration of action: average of 90 minutes; ranges from 30–120 minutes Concentration: 100 µg/mL
Naloxone	Opioid overdose: 0.4–2 mg Pediatrics: 0.1 mg/kg	Time of onset: 2–3 minutes Half-life: 125 minutes Concentration: 0.2–2.0 mg/mL
Flumazenil	Benzodiazepine reversal: 0.025 µg/kg, up to 400 µg/dose	Time of onset: 1–3 minutes Duration of action: 122 minutes Concentration: 0.1–1.0 mg/mL
Oxymetazoline and lidocaine mixture	Oxymetazoline 1.0–1.5 mL 4% lidocaine 0.5 mL	Can be used in combination or just lidocaine can be used for epistaxis, nasogastric intubation, and nasogastric tubes

Source: Compiled from references 1–54.

as an effective reversal agent for opiate overdose.³⁰ Intranasal naloxone administration before hospital arrival decreases opiate-related deaths.³¹ Intranasal administration is effective and offers a needleless administration alternative.³² Flumazenil may be administered intranasally for benzodiazepine reversal.^{3,33,34}

SEIZURES

Intranasal midazolam is effective for seizure termination in the home, prehospital setting, and ED.^{35–39} Intranasal administration is better tolerated by patients and families than rectal administration.^{35–38} Intranasal midazolam is frequently used in the author's ED for seizure termination in pediatric and adult patients when IV access is delayed.

OTHER USES

Intranasal medications have been used for many other diseases. Lidocaine has been used to treat migraine headaches.⁴⁰ Anesthesia of the nasal cavity is used prior to epistaxis management, nasogastric intubation, and nasotracheal intubation.⁴¹ Other medications are used for intranasal treatment of migraines (e.g., dihydroergotamine, hydroxocobalamin, rizatriptan, sumatriptan, and zolmitriptan).⁴² Ketorolac has been used successfully to treat pain.⁴³ Intranasal midazolam has broken cyanosis associated with tetralogy of Fallot spells.⁴⁴ Ketamine is used on the violent or agitated patient.⁴⁵ Vaccines, steroids, and desmopressin for diabetes insipidus have all been successfully used intranasally.⁴⁶ Intranasal glucagon has been used for insulin-associated hypoglycemia.^{47,48} These uses of intranasal medication administration may eventually be used routinely

in the prehospital setting and in the ED. More uses of intranasal medications can be found at www.intranasal.net.

CONTRAINDICATIONS

A large amount of blood or mucus in the nasal passages limits nasal absorption. Intranasal medication administration is not recommended with significant maxillofacial trauma.

EQUIPMENT

- Medication to be administered in appropriate dose and concentration
- Syringe
- Mucosal atomizer device (Table 201-4 and Figure 201-1)

Atomizer devices are often available in the ED. Many devices or available commercially. These are disposable devices that are single patient use (Figure 201-1 and Table 201-4). Popular devices are the LMA MAD line of mucosal atomizer devices (Teleflex Medical, Morrisville, NC). There are multiple devices for all topical needs (Figure 201-1). The devices make the particle size approximately 30 to 100 μm to enhance absorption through the nasal mucosa.

PATIENT PREPARATION

Explain the risks, benefits, and potential complications of the procedure to the patient and/or their representative. Advise adult patients of the planned route of medication administration and provide a description of the expected procedure to maximize cooperation. Some consider obtaining an informed consent for the

TABLE 201-4 Some of the Nasal Atomizers Commercially Available*

Name	Manufacturer	Comments
DeVilbiss Model 15 Medical Atomizer	DeVilbiss Healthcare	Disposable and reusable versions Adjustable tip
Enk Fiberoptic Atomizer Kit	Cook Medical	Pressure-resistant oxygen tubing Atomizes through fiberoptic bronchoscope working channel
EZ-Spray	Alcove Medical	Disposable Trigger valve system
LMA MADdy Pediatric Mucosal Atomizer Device	Teleflex Medical	Disposable single use Comes in various colors and shapes Child friendly Attaches to standard syringe 11.4 cm long
LMA Bottle MADomizer Atomizer	Teleflex Medical	Disposable single-use tips Reusable bottle 10 cm long
LMA MADgic Laryngo-Tracheal Atomizer	Teleflex Medical	Disposable single use Attaches to standard syringe Flexible tube 21.6 cm long
LMA MAD Nasal-Intranasal Mucosal Atomizer Device	Teleflex Medical	Disposable single use Attaches to standard syringe

*Some of these devices are not used in the Emergency Department due to the requirement of sterilization between patients.

administration of nasal medications. This is considered because the patient and nursing staff are not as accustomed to intranasal administration of medication. Pediatric patients may need an appropriate distraction or physical restraint (Chapter 232).

FIGURE 201-1. Some common nasal atomizers for topical nasal anesthesia. A. The LMA MAD nasal. B. The LMA MADgic laryngeotracheal. C. The child's LMA MADdy. D. The MADomizer.

FIGURE 201-2. The administration of intranasal medication using the LMA MAD. (Photo courtesy of www.intranasal.net.)

Apply cardiac monitoring, a noninvasive blood pressure cuff, and pulse oximeter if indicated. Parents use nasal midazolam at home in high concentration without any monitoring.³⁵ **Sufentanil is the exception and the patient must be monitored.** Sufentanil is more potent than fentanyl, rapidly absorbed through the nasal mucosa, and nasal administration can result in respiratory depression, sedation, and apnea (verbal discussion with T. Wolfe, MD, from www.intranasal.net). Place the patient in a position of comfort (e.g., sitting upright, semirecumbent, or supine). Examine both nares and suction out any blood and/or mucus. **Avoid the nasal cavity if any anatomic abnormalities are noticed.** Draw up the medication to be administered. Use the highest concentration of the medicine to limit the volume administered.

TECHNIQUE

The technique of nasal medication administration is easy, quick, and simple. Position the patient so there is easy access to the chosen nasal cavity. Gently insert the nasal mucosal atomizer device into the patient's nostril (**Figure 201-2**). Apply the medication briskly using the syringe attached to the atomizer or other atomizer device. The brisk application increases atomization, limits dripping of the medication into the nasopharynx, improves efficacy, and minimizes choking. Remove the device from the patient's nostril and allow the medication to take effect. Wipe any drips from the nostril.

ASSESSMENT

Give the medication several minutes to work. The time allowed depends on the medication given and the time for it to work. **Repeat the medication dose if there is no effect, if the patient shows no adverse side effects, and if below the maximum dose. Always remember that all the medication administered intranasally contributes to the maximum dose whether or not the patient shows the desired effect.**

AFTERCARE

Close observation of the patient is recommended after intranasal medication administration. Discourage the patient from blowing their nose or sniffing for several minutes. This ensures the proper time for the medication to be absorbed through the nasal mucosa.

COMPLICATIONS

The most commonly reported complications of intranasal medication administration are bad taste and vomiting.⁴ Patients will often experience a burning sensation upon administration of

nasal medication. This usually dissipates within several minutes. No cases of respiratory depression or oversedation were reported with the administration of appropriately dosed intranasal fentanyl in children.⁴ **This does not imply that these complications never happen.** Intranasal medication administration is generally considered to be as safe as other routes of medication administration.

SUMMARY

Intranasal administration of certain medications for analgesia, anxiolysis, seizure termination, and opiate reversal is safe and effective in children and adults. Intranasal administration may decrease time to medication delivery and decreases the need for IV access. Use of an atomization device is recommended. Careful attention to the volume and dose of medication delivered to each nasal cavity is necessary for maximum efficacy.

Nasal Foreign Body Removal

G. Carolyn Clayton, Katarzyna M. Gore,
and Melissa M. Rice

INTRODUCTION

Nasal foreign bodies are commonly seen in children, particularly those between 1 and 4 years of age. Young children are naturally curious and spend a great deal of time investigating themselves and the world around them. This involves handling, tasting, and smelling whatever they get their hands on. The Emergency Physician is faced with a foreign body in the nose when these investigations go too far. Adult patients with mental disabilities or psychiatric illness can present with a nasal foreign body. The most common foreign bodies found are beads, food (e.g., corn, nuts, peas, and popcorn), paper, rocks, and toy parts.^{1,2} Nasal foreign bodies result from attempts to clean the nasal cavity or to control bleeding with cotton swabs, paper, or sponge material.³

Children may present with a known nasal foreign body. Other presentations may be subtle. This includes an odor, halitosis, persistent unilateral nasal discharge, or recurrent epistaxis. Foreign bodies can be found incidentally during a routine examination or on radiographs in the asymptomatic child.^{1,4-6}

The task of the Emergency Physician is fourfold.^{7,8} Suspect the presence of a nasal foreign body. Perform a thorough physical examination, including a search for the foreign body. Visualize the foreign body. Remove the foreign body efficiently and with minimal trauma.

ANATOMY AND PATHOPHYSIOLOGY

The nasal cavity consists of two passages on either side of the nasal septum. The superior, middle, and inferior bony turbinates project medially into each passage and are covered by a mucous membrane overlying a venous plexus. Foreign bodies can be located anywhere in the nose. Most foreign bodies are found on the floor under the inferior turbinate or anterior to the middle turbinate.⁹ The cartilaginous septum is covered by a thin mucosa and receives its blood supply from the overlying mucoperichondrium. Sensory nerves of the nasal cavity are branches of the greater palatine nerve and sphenopalatine ganglion.¹⁰ These nerves are easily numbed with topical anesthetics. The nasal cavity is separated from the orbit by the thin lamina papyracea and from the anterior cranial fossa by the cribriform plate of the ethmoid bone. See Chapter 203 on nasal fracture reduction and Chapter 205 on epistaxis for a more detailed review of nasal cavity anatomy.

A foreign body in the nasal cavity sets off an inflammatory response and the venous plexus becomes congested. Swelling may eventually obscure the foreign body from view. The longer the foreign body remains in the nasal cavity, the more likely the patient is to develop pressure necrosis, granulation tissue, infection, and a purulent discharge. The foreign body can erode into the surrounding tissues over time if it is not removed. A unilateral malodorous discharge and/or epistaxis from a child's nose is a sign of a foreign body.

INDICATIONS

All nasal foreign bodies must be removed to prevent complications. The direct observation of a foreign body in one or both nostrils is an indication for its removal. The presence of signs or symptoms such as unilateral persistent nasal discharge, recurrent unilateral epistaxis, halitosis, or an unusual body odor should prompt a search for a nasal foreign body. Imaging studies are not routine but may be useful in a symptomatic patient where direct visualization is not possible or inconclusive.¹¹ More than 90% of nasal foreign bodies can be removed by the Emergency Physician with readily available equipment.^{1,4,8}

The presence of a disk or button battery in the nasal cavity requires urgent removal.¹²⁻¹⁵ These batteries contain a strong alkali, usually potassium hydroxide or sodium hydroxide. The moisture in the nasal cavity may cause corrosion of the battery, leakage of the battery contents, and a low-voltage direct current between the anode and cathode. This may cause liquefaction necrosis, tissue electrolysis, and tissue destruction (i.e., mucosa, cartilage, and bone) within hours.^{10,16} These patients need to be seen and followed by an Otolaryngologist after the battery is removed. An electrical thermal burn may cause damage to the nasal tissues that is more extensive than is visible initially.^{17,18} Patients may develop a delayed septal perforation and alar collapse from extensive tissue damage.¹⁹

Small magnets can produce pressure necrosis in the tissues. This is particularly true if they span both sides of the cartilaginous septum or a turbinate. Magnets are commonly used as beads, as clasps for necklaces and bracelets, and in faux piercings.^{20,21}

CONTRAINDICATIONS

There are a few contraindications to the removal of a nasal foreign body in the Emergency Department. One contraindication is if the airway is in danger. **Do not attempt to retrieve a nasal foreign body if the patient is in distress or unstable.** This might be due to a posteriorly placed foreign body or an uncooperative patient. **Management of the airway in the Emergency**

Department or in the Operating Room must take priority to foreign body removal.

Consult an Otolaryngologist in patients with nasal foreign bodies that are impacted, cause excessive bleeding, or have resulted in nasal perforation or penetration. Foreign bodies located posterior and superior to the middle turbinate pose a risk of being pushed back during retrieval and may perforate the cribriform plate. Larger foreign bodies entering the nose traumatically should be removed by an Otolaryngologist as they may have penetrated the cranial cavity, the orbit, or a sinus cavity.^{22,23} Other indications to consult an Otolaryngologist include failure of the Emergency Physician to remove the foreign body after repeated attempts, failure to properly sedate the patient, or the inability to sedate the patient. These contraindications may require foreign body removal in the Operating Room under more controlled circumstances and with equipment not available in the Emergency Department.

EQUIPMENT

■ NASAL ANESTHESIA AND VASOCONSTRICTION

- 1% or 2% lidocaine solution
- 4% lidocaine solution with 0.25% phenylephrine
- 4% cocaine
- 0.25% phenylephrine (e.g., Neosynephrine)
- 5 mL syringe
- Cotton pledgets
- Atomizer device, if available

■ MANUAL REMOVAL OF FOREIGN BODY (FIGURE 202-1)

- Head light or head mirror, surgical lamp, or overhead light
- Nasal speculum
- Alligator forceps
- Hartman forceps
- Bayonet forceps
- Lighted forceps (Bionix Medical Technology, Toledo, OH)
- Frazier suction catheter

FIGURE 202-1. Instruments used for the manual extraction of a nasal foreign body. Top row (from left to right): disposable medicine cup, pledgets, nasal decongestant spray. Bottom row (from left to right): 0° telescope, bayonet forceps, nasal speculum, 90° blunt-tipped ear pick or mastoid probe, small alligator (ear) forceps, and large alligator or Blakesley forceps.

- Ear curette
- Blunt mastoid hook
- Wire loop

■ CATHETER REMOVAL OF A FOREIGN BODY

- Fogarty vascular catheter, size #4 or #5
- Foley catheter, 5 to 6 French
- 5 mL syringe
- Katz Oto-Rhino Extractor (InHealth Technologies, Carpinteria, CA)

■ POSITIVE PRESSURE

- Cooperative parent
- Bag-valve device
- Face mask, various sizes
- Male-male tube adapter

■ CYANOACRYLATE TISSUE ADHESIVE

- Cyanoacrylate tissue adhesive
- Cotton-tipped applicator
- Cyanoacrylate removal equipment (Chapter 197)

■ MAGNET REMOVAL

- Pacemaker magnet
- Metallic medical instrument
- Household magnet

■ NASAL WASH

- Bulb syringe
- Normal saline

■ PEDIATRIC IMMOBILIZATION

- Sheets
- Commercial immobilization device (e.g., Papoose board) (Chapter 232)

PATIENT PREPARATION

Discuss the risks, benefits, complications, and different techniques available with the patient and/or their representative. Include the possibility of using procedural sedation initially or if initial attempts at removal are unsuccessful. Obtain a signed informed consent for the removal procedure and the procedural sedation.

The type, shape, size, and location of the foreign body are important factors to consider in choosing the most appropriate technique. The patient's age and ability to cooperate during the examination and removal and the experience and skill of the Emergency Physician can influence the choice of techniques.

Observe universal precautions, especially eye protection, while working in proximity to the mucous secretions of the airway. It is recommended to wear a gown, gloves, and a face mask with an eye shield or goggles. **Carefully inspect both nasal cavities for foreign bodies before and after the mucosa is decongested.** A child will sometimes insert foreign bodies up both nostrils. A good light source is indispensable for examining the nasal cavity and removing the foreign body.

Preparation is important to ensure that the first attempt at retrieval is successful. Have a variety of equipment readily available at the bedside if additional attempts and techniques are required.

Have a Frazier suction catheter to clear the nasal passages of blood and/or mucus. **A good hands-free light source (i.e., overhead light or a head lamp) is important in directly visualizing the foreign body and facilitating its removal.**

Anesthesia of the nasal mucosa is obtained by the topical application of lidocaine to a maximum of 4 mg/kg or cocaine to a maximum of 3 mg/kg. Cocaine has the added benefit of vasoconstriction and decongestion of the nasal mucosa. Add a vasoconstrictive agent (i.e., epinephrine or phenylephrine) to lidocaine if no contraindications exist. A syringe can be used as a dropper to apply the medication intranasally (Chapter 201). This is best done by administering several drops at a time and then reassessing visibility before adding more. **The patient is more apt to blow the medication out their nose before it can take effect if the entire dose is added at one time.** An atomizer may be used. Some of these devices attach to a syringe or a nasal decongestant container. Atomizers are disposable devices that are single patient use (**Figure 201-1** and **Table 202-1**). A popular device is the MAD line of mucosal atomizer devices (LMA North America, San Diego, CA). They make multiple devices for all topical needs. Allow 5 to 10 minutes for the medication to take effect.

It would be appropriate to have the patient attempt to blow the foreign body out of their nostril if the patient is cooperative. Have the patient sit up and lean forward. Instruct the patient to blow forcefully through their nose while covering the uninvolvement nostril with a finger. Even if this has failed at home, it may work with the nasal mucosa swelling alleviated by the decongestants.¹⁹

Most children will need to be restrained while the foreign body is being removed. The child who appears cooperative and is adequately anesthetized may move suddenly while instruments are in the nasal cavity. One method is for the child to sit on their parent's lap (**Figure 202-2**). The adult should cross their legs over the child's legs, using one arm to restrain the child's arms and trunk and the other arm to hold the child's forehead (**Figure 202-2**). Alternatively, instruct an assistant to hold the patient's head while the parent controls the body and limbs. Another alternative is to wrap the child in

TABLE 202-1 Some of the Commercially Available Atomizers

Name	Manufacturer	Comments
DeVilbiss Model 15 Medical Atomizer	DeVilbiss Healthcare	Adjustable tip Disposable and reusable versions
Enk Fiberoptic Atomizer Kit	Cook Medical	Atomizes through fiberoptic bronchoscope working channel Pressure-resistant oxygen tubing
EZ-Spray	Alcove Medical	Disposable Trigger valve system
LMA MADdy Pediatric Mucosal Atomizer Device	Teleflex	11.4 cm long Attaches to standard syringe Child friendly Comes in various colors and shapes
LMA Bottle MADomizer Atomizer	Teleflex	Disposable single use 10 cm long Disposable single-use tips Reusable bottle
LMA MADgic Laryngo-Tracheal Atomizer	Teleflex	21.6 cm long Attaches to standard syringe Disposable single use Flexible tube
LMA MAD Nasal-Intranasal Mucosal Atomizer Device	Teleflex	Attaches to standard syringe Disposable single use

FIGURE 202-2. Method to properly restrain a child.

a sheet or use a commercial restraint device (e.g., Papoose board) (Chapter 232).¹⁹

Uncooperative patients may require anxiolysis, procedural sedation (Chapter 159), or general anesthesia prior to removal of the foreign body. Procedural sedation may be used to facilitate foreign body removal in the uncooperative or fearful patient. Approximately 21% of pediatric patients with nasal foreign bodies required procedural sedation.⁴ The nasal foreign body was successfully removed in 95% of these cases. Ketamine was the most commonly used agent.

TECHNIQUES

DIRECT INSTRUMENTATION OR MANUAL REMOVAL

The most straightforward and common method is to remove the anteriorly located nasal foreign body under direct vision. Do not attempt instrument removal if the foreign body is located posteriorly. The instruments most often used include alligator forceps, bayonet forceps, straight forceps, or mosquito forceps. Hooked probes (e.g., right angle or curved hooks, ear curettes, wire loops, or mastoid hooks) can be utilized. A novel device is the Lighted Forceps for Foreign Body Removal (Bionix Medical Technologies, Toledo, OH). It is a single patient use and disposable device that contains a light source and acts like forceps (**Figure 202-3**).

The EasiEar Disposable Comfort Curette (Splash Medical Devices LLC, Atlanta, GA) is an improvement to the standard disposable plastic curette (**Figure 202-4**). It is a stainless steel, single patient use,

FIGURE 202-3. The Lighted Forceps for Foreign Body Removal. (Photo courtesy of Bionix Medical Technologies, Toledo, OH.)

and disposable curette. The rounded wire head is smooth. It lacks the jagged and sharp plastic edges that are often found on molded plastic curettes. The EasiEar has no abrasive edges, seams, or surfaces to potentially abrade the nasal mucosa. This design may prevent abrasions, bleeding, and lacerations. The spring wire shaft provides flexibility and enhanced maneuverability when compared to molded plastic curettes. The angled head and flexible shaft allow it to be manipulated within the nasal cavity to remove a foreign body.

The above instruments enable the Emergency Physician to grasp the foreign body directly or pull it out from behind. Anteriorly located foreign bodies are often easily removed with instrumentation. Forceps are better suited for soft and irregularly shaped foreign

FIGURE 202-4. The EasiEar Metal Curette (Splash Medical Devices LLC, Atlanta, GA).

FIGURE 202-5. Using forceps to remove a thumb tack lodged in the nostril.

bodies (**Figure 202-5**).^{9,24} Curettes and hooks are more effective for hard and spherical foreign bodies.^{9,24}

Insert the nasal speculum to hold the nostril open. Adjust the headlight or head mirror to illuminate the nasal cavity. **It cannot be overemphasized how crucial adequate light and visibility are to successfully remove the foreign body.** Remove any mucus or blood with the Frazier suction catheter. Grasp an irregularly shaped foreign body with forceps (**Figure 202-5**). Forceps may cause a round or smooth foreign body to slip farther posteriorly when the jaws close. Pass a curette, wire loop, or mastoid hook behind a round or smooth foreign body and pull it out (**Figure 202-6**).^{19,25} The jaws of a small alligator forceps can be passed through the opening of a bead if it is facing outward (**Figure 202-7**). Open the jaws when they are beyond the lumen of the bead and pull the bead from the nasal cavity.

Relative contraindications to instrumentation include posteriorly located foreign bodies, friable foreign bodies, round foreign bodies, and smooth foreign bodies. Potential complications include posterior displacement of the foreign body leading to aspiration, epistaxis, lacerations, mucosal abrasions, and nasal obstruction.

BALLOON CATHETER EXTRACTION

Some Emergency Physicians prefer to use a catheter with a balloon to pull foreign bodies from the nasal cavity. This technique has a reported success rate of 90% and is used most successfully for foreign bodies that are round, smooth, and cannot be grasped readily.²⁶ **A balloon catheter does not work if the foreign body fully obstructs the nasal passage.** Authors describe using a variety of catheters

FIGURE 202-6. Removing a round, smooth foreign body from the nasal cavity. The curette, mastoid hook, or wire loop is passed through the nares and behind the foreign body. The hook is used to pull the foreign body out of the nasal cavity.

(e.g., a #4 to #8 Fogarty vascular catheter, a #6 Fogarty biliary catheter, and a 5 to 6 French Foley balloon catheter).^{4,19,27,28}

Test the balloon on the catheter device. Inflate the balloon to ensure it has no leaks. Deflate the balloon. Lubricate the catheter. Insert the catheter until the balloon is beyond the foreign body. The catheter may be placed above, below, or to the side of the foreign body.¹⁹ Inflate the balloon with 2 to 3 mL of air. Gently pull the catheter. The balloon will push the foreign body out of the nostril. A balloon catheter can be used to stabilize a foreign body from behind while it is removed with forceps.

The disadvantages of this method are that it is more traumatic and epistaxis is more common.² The Emergency Physician risks pushing the foreign body posteriorly and impacting it, obstructing the nasal passage, or dislodging it into the airway if the catheter is not passed under direct visualization or if it is too large to pass around the foreign body.

KATZ EXTRACTOR

The Katz Extractor Oto-Rhino Foreign Body Remover (InHealth Technologies, Carpinteria, CA) is a device designed to extract foreign bodies from the nasal and auditory passages (**Figure 202-8**). It is a disposable, single-use device consisting of a balloon-tipped catheter attached to a syringe. Always test the device before using it. Push the plunger to inflate the balloon and inspect it for any air leaks. Release the plunger to deflate the balloon.

FIGURE 202-7. An alligator forceps is used to remove a bead or other foreign body with a hollow center.

FIGURE 202-8. The Katz Extractor. The balloon at the tip inflates and deflates by pushing and releasing the plunger, respectively. (Photo courtesy of InHealth Technologies, Carpinteria, CA.)

Grasp the device with the dominant hand (**Figure 202-9**). Gently insert the catheter along the wall of the nasal cavity until the balloon is just past the foreign body (**Figure 202-9A**). Inflate the balloon by depressing the plunger on the syringe (**Figure 202-9B**). Withdraw the catheter and foreign body from the nasal cavity while maintaining the balloon in the inflated state (**Figure 202-9C**). Insert the catheter through the hole, rather than behind it, and inflate the balloon if the foreign body has a central hole (e.g., candy or bead).

FIGURE 202-9. The Katz Extractor removing a nasal foreign body. **A.** The device is inserted until the balloon is just past the foreign body. **B.** The balloon is inflated. **C.** The Katz extractor is removed with the balloon inflated and the foreign body is removed.

FIGURE 202-10. The Hognose otoscope tip attached to an otoscope. (Photo courtesy of IQDr. Incorporated, Manitou Springs, CO.)

HOGNOSE OTOSCOPE TIP

The Hognose (IQDr. Incorporated, Manitou Springs, CO) is a disposable, latex-free, single-use device that attaches to a standard otoscope (**Figure 202-10**). It comes in three sizes (i.e., 3, 4, and 5 mm) with a color-coded tip. The size represents the cup size at the tip of the device. The tip is soft, self-molding, and looks like the nose of a hog. It has an insufflation port and suction tubing attached to its side. The adapter on the suction tubing attaches to standard wall suction tubing.

Attach the Hognose to the otoscope as if attaching a disposable speculum to an otoscope. Turn on the otoscope light source. Attach the hognose tubing to suction tubing and a suction source. Turn the suction source to low or medium. Grasp the otoscope with the dominant hand. Insert the Hognose into the nasal cavity while visualizing the foreign body through the otoscope head. Place an index finger over the insufflation port to engage the suction at the device tip when it is next to the foreign body. Gently advance the otoscope until the tip of the Hognose is against and attached to the foreign body. The soft tip has collapsed on itself if you suddenly see black through the otoscope. Remove the finger over the insufflation port and reapproach the object. Withdraw the Hognose with the foreign body attached while maintaining suction.

GATORNOSE OTOSCOPE TIP

The Gatornose (IQDr. Incorporated, Manitou Springs, CO) is a disposable, latex free, single-use device that attaches to a standard otoscope (**Figure 202-11**). It twists onto an otoscope like a speculum. It comes with three different jaw types that attach to the body of the

FIGURE 202-11. The Gatornose base attached to an otoscope. Note the three types of jaws that are available to snap onto the base of the device. (Photo courtesy of IQDr. Incorporated, Manitou Springs, CO.)

device. These jaws are small flat jaws, large flat jaws, and open loop jaws. A trigger on the body of the device controls jaw opening and closing.

Attach the Gatornose base to the otoscope as if attaching a disposable speculum to an otoscope. Apply the appropriate arms onto the Gatornose base. Turn on the otoscope light source. Grasp the otoscope with the dominant hand. Insert the ring finger into the trigger. Pull the trigger to close the Gatornose jaws. Gently insert the Gatornose jaws just into the nasal cavity. Push the trigger to open the Gatornose jaws and view the nasal cavity through the otoscope. Gently advance the otoscope while visualizing the foreign body through the otoscope head. Position the jaws above and below or anterior and posterior to the foreign body. Pull the trigger to close the jaws onto the foreign body. Withdraw the otoscope with the foreign body in the jaws of the Gatornose.

SUCTION TECHNIQUE

Frazier suction catheters are most useful with small or round foreign bodies where suction can be maintained between the device and the foreign object. Suction is relatively contraindicated if the foreign body is shaped so that the suction device cannot form a seal or if the foreign body is friable. This technique will be otherwise unsuccessful or will push the object farther into the nasal cavity. This technique is best reserved for large, round foreign bodies where suction can be maintained between the device and the foreign body. Complications include trauma to the surrounding tissues and epistaxis.²⁹

Attach the Frazier suction catheter to the suction tubing. Turn on the suction source to at least 100 mmHg. Gently insert the catheter into the nasal cavity. Place a thumb over the hole in the catheter handle to direct the suction through the tip of the catheter. Gently advance the suction catheter until the tip is in contact with the foreign body. Withdraw the Frazier suction catheter and foreign body from the nasal cavity.

Use suction with plastic intravenous tubing for impacted smooth, spherical objects.³⁰ Cut a short length of plastic intravenous tubing and attach one end to the suction source. Fashion the other end into a small flange shape using a heat source and any metal object with a rounded end (e.g., the tip of a hemostat or larger clamp). Heat the jaws of the hemostat and insert them into the plastic tubing just enough to create a flange. Turn on the suction source. Place a

hemostat onto the tubing to temporarily clamp the suction tubing. Gently advance the flange tip into the nasal cavity until it contacts the foreign body taking care not to push it inward. Have an assistant remove the hemostat from the tubing to activate the suction. Gently but quickly remove the tubing and attached foreign body from the nasal cavity.

POSITIVE PRESSURE

This technique is best utilized for foreign bodies that are large, posteriorly located, or occlude the nasal passage.³¹⁻³³ It involves the generation of positive pressure in the nasopharynx behind the foreign body to force it out of the nostril. There are several ways to generate positive pressure within the nasal cavity. One is to simply ask the patient to occlude the unaffected nostril, take a deep breath through their mouth, close their mouth, and then forcefully exhale the air out through the nostril with the foreign body while keeping their mouth closed. This technique is most successful in adolescents and adults who are cooperative and can coordinate the movements. The advantage to this technique, if it is successful, is that no instruments are placed into the nose. The disadvantage is that the foreign body can be forcefully expelled from the nasal cavity. Eye protection is advised.

Other variants of this technique have been developed. The “big kiss” is also known as the “mother’s kiss,” “parent’s kiss,” or “mouth-to-mouth” technique (Figure 202-12).³⁴⁻³⁹ It involves asking the parent to blow into the child’s mouth. This is like rescue breaths during cardiopulmonary resuscitation (CPR). Explain the procedure to the child and the parent. Instruct the parent to open the child’s mouth with one hand and stabilize the chin while occluding the unaffected nostril with a finger from their other hand. Instruct the parent to open their mouth, take a big breath, and then place their mouth over the child’s open mouth. The child’s mouth must be completely covered by their parent’s mouth and a good seal formed. Instruct the parent to deliver a sudden and forceful breath into the child’s mouth.

FIGURE 202-12. The “mother’s kiss.” (Photo used with permission from reference 34.)

This entire sequence of events should only take 3 to 4 seconds to complete.

This maneuver causes the child's glottis to close. The foreign body will be expelled from the affected nostril if enough pressure is generated. This technique may be less traumatic to the child and involves no instrumentation or restraint.³⁴⁻³⁹ High success rates have been reported.³⁴⁻³⁹ This technique may be difficult for some parents to perform.

A modified version of this technique involves using a drinking straw or small tube between the child's mouth and parent's mouth.³¹ The parent gives a big puff of air through the straw while the child tries to make a tight seal between their mouth and the straw. The Emergency Physician can perform this technique without placing their mouth on the child's mouth.³¹

A bag-valve-mask device (i.e., the Ambu-bag) can be used to blow the foreign body out of the nostril.⁴⁰ Choose a face mask that is small enough so that it only covers the patient's open mouth. Cover the patient's mouth tightly with the mask. Close the unobstructed nostril with a finger (**Figure 202-13**). Squeeze the bag to force air into the mouth and lungs and out the nose.⁴⁰ A variant of this method uses an anesthesia bag connected to high-flow oxygen at 10 to 15 L/min. Cover the mouth with the mask, close the thumb hole, and allow the bag to expand and gradually increase the airway pressure. If this does not expel the foreign body, compress the bag.⁴

The "Beamsley Blaster" technique makes use of the positive pressure generated from the application of high-flow oxygen at 10 to 15 L/min from tubing attached to an oxygen wall outlet.^{41,42} The other end of the tubing is attached to a male-male adapter that is inserted into the unaffected nostril. The set-up generates enough pressure in the posterior nasopharynx to dislodge the foreign body from the nostril. The patient's mouth must be closed during the procedure to create a seal. There were no complications noted in the initial study. A subsequent case of barotrauma (e.g., subcutaneous orbital emphysema) has been reported.⁴³ An alternative is to use a 60 mL syringe with air.

Positive-pressure methods are contraindicated if there are foreign bodies in both nasal passages. It is important to be sure that

FIGURE 202-13. Bag-valve-mask method of removal. The child is restrained and the contralateral nostril is occluded. Bag-valve-mask is applied on the mouth to create a seal and a few breaths are delivered until the foreign body is expelled.

air is forced in the open nasal cavity or the foreign body could be blown into the trachea or esophagus. Blow short puffs of air during the child's cries. The soft palate will close when the child is vocalizing and direct both the air and the foreign body out of the other nostril.²

CYANOACRYLATE TISSUE ADHESIVE ASSISTED REMOVAL

Cyanoacrylate tissue adhesive can be used to extract spherical and other solid foreign bodies that are visible.⁴⁴ This technique can be fraught with complications. There is a chance of gluing the foreign body to the nasal mucosa as well as creating a glue foreign body. The foreign body can be further impacted if pushed posteriorly or fall into the oropharynx and aspirated.

Obtain a cotton-tipped applicator. Moisten the tip of the applicator stick with a very tiny amount of cyanoacrylate glue. A larger amount can drop off into the nasal cavity. Insert the applicator stick before the glue dries and until it just touches the foreign body. Maintain this position for 30 to 60 seconds to allow bonding of the glue to the foreign body. Do not allow the drop of glue to fall from the stick and bond to the nasal mucosa. Do not touch the tip of the wooden applicator stick to the nasal mucosa as it will bond to the mucosa. Remove the applicator stick with the foreign body attached. The main disadvantages of this technique are potential bonding of the nasal mucosa and the time it takes for the glue to bond to the foreign body.

ALTERNATIVE TECHNIQUES

NASAL WASH

The nasal wash technique involves the introduction of high-pressure normal saline through a bulb syringe into the unaffected nasal cavity. It is best used with friable and nonorganic materials that are posterior in location.³¹ Place approximately 7 mL of normal saline into a bulb syringe. Insert the bulb syringe into the unaffected nostril. Advance the bulb syringe into the nostril until a seal is created. Forcefully squeeze the bulb syringe. The pressure generated is believed to expel the saline and the foreign body from the other nostril.

The use of this technique carries a high risk of aspiration of saline and the foreign body. The saline may reflux into the sinuses or eustachian tubes. Its use should be restricted to older patients who can cooperate and protect their airway.^{11,45} **Do not use this technique in patients with a button battery or organic matter in their nasal passages.** The increased moisture will hasten corrosion of the battery and cause swelling of the organic matter making additional attempts at removal more difficult. Do not use this technique in young infants, those with airway abnormalities, or those with neurologic abnormalities.

MAGNET REMOVAL

An occasional patient will present with a mini-magnet adhered to the nasal mucosa. The source of the magnets can be from their insertion in young children or nasal jewelry.²⁰ Adherence of magnets across the nasal septum creates the potential for septal necrosis and perforation.^{21,46,47} They may be difficult to remove because of the attractive force created across the nasal septum.

Numerous methods can be used to facilitate magnet removal. They may be grasped with a variety of forceps or hemostats. A hook can be made from a nonferromagnetic blunt probe.²⁰ A magnet can be used to facilitate nasal magnet removal.^{21,48,49} A pacemaker

FIGURE 202-14. Hydration of expanding beads.

magnet is readily available in most Emergency Departments. A small and strong household magnet may be available from the hospital maintenance department. Metallic objects that are ferromagnetic may be removed with the aid of other magnets. One method includes magnetizing a medical instrument (e.g., forceps or a hemostat) by placing it in series with a pacemaker magnet. The instrument can then be placed in the nasal cavity to attract the metallic foreign body. Another method is to use a household magnet at the entrance of the nasal cavity in attempts to attract the foreign body. The strength of the magnet and the distance of the object may limit this method.^{48,50}

EXPANDING BEADS

These beads are small, brightly colored, and resemble candy. The beads swell when in contact with liquids (e.g., nasal secretions or water) (Figure 202-14).^{51,52} These are commonly used as decorations, to preserve flowers, and as toys. Children can smell the beads to determine if they are flavored and accidentally inhale them into their nose. They can be difficult to remove when swollen. Do not use fluid irrigation techniques in removing these foreign bodies.

ASSESSMENT

Inspect the nasal cavity for any remaining fragments of the foreign body, abrasions, bleeding, lacerations, a second foreign body, or ulcerations. A gray precipitate may be noted if a disk battery has been removed. Irrigate the nasal cavity with saline after a battery is removed to eliminate any electrolyte solution or precipitate to prevent further damage.²² Bleeding can be controlled with topical phenylephrine or epinephrine, pressure, or any of the methods described to control epistaxis (Chapter 205).

AFTERCARE

Discharge the patient home with nasal saline spray to the affected nostril until secretions are clear of blood or pus. Oral antibiotics may be prescribed if the patient has developed sinusitis from a retained foreign body. Patients with ulcerations on opposing sides of the

nasal cavity must be followed-up to prevent obstructive synechiae or adhesions from forming. Patients with button batteries removed, mini-magnets removed, injuries, or complications should follow-up with an Otolaryngologist. Educate the caretakers to remove any small objects from the child's reach, supervise children when they have access to small objects, and childproof the house.

COMPLICATIONS

Complications can arise from the nasal foreign body or the removal technique.^{15,16} Foreign bodies can cause aspiration, epistaxis, infection, nasal obstruction, perforation, pressure on surrounding tissues, or ulceration.⁹ The risk of complications increases the longer the foreign body is present. Epiglottitis, facial cellulitis, meningitis, orbital cellulitis, otitis media, and sinusitis have been associated with retained nasal foreign bodies.^{9,18}

The most significant complication would be to dislodge the foreign body into the airway. This is most likely to occur in an uncontrolled situation. Placing the patient supine and in the Trendelenburg position may prevent accidental aspiration of the foreign body.⁵³ **Consider the use of sedation, procedural sedation (Chapter 159), or general anesthesia if the patient is uncooperative.**

Potential complications associated with each technique were described with each specific technique.⁵⁴ Aspiration from posterior dislodgment of a nasal foreign body remains a serious potential complication for all of the techniques. Positive-pressure techniques can result in barotrauma. Periorbital emphysema has been described using the "Beamsley Blaster" method.⁴³ Secondary infection may result from the procedure. Antibiotics are generally not indicated in most cases once the foreign body has been removed. Complications related to manipulation within the nasal cavity include bleeding or subsequent infection. An anterior nasal pack may be required in rare instances to tamponade bleeding. Toxic doses of cocaine and/or lidocaine may result in cardiac arrhythmias and seizures.

SUMMARY

Most nasal foreign bodies can be safely removed by the Emergency Physician with instruments that are readily available in the Emergency Department. There are multiple techniques for removing foreign bodies from the nasal cavity. Each has its own advantages and disadvantages. These methods include the use of balloon catheters, forceps, and positive pressure. Choose the method according to the shape and location of the foreign body, the tools available, the cooperativeness of the patient, and experience with the different removal techniques.

Nasal Fracture Reduction

Eric F. Reichman

INTRODUCTION

Nasal fractures due to blunt trauma are a common occurrence (**Figure 203-1**). Fights, auto accidents, and sports accidents account for most fractures in an urban setting.¹⁻⁴ Work, farm, sports, or leisure activity accidents account for most of these injuries in rural

FIGURE 203-1. A photograph of a patient with a nasal fracture. (Used with permission from Shah BR, et al: *The Atlas of Pediatric Emergency Medicine*, 2nd ed. New York: McGraw-Hill; 2013.)

areas.⁵ The majority of nasal fractures occur in males aged 15 to 25 years old, with fights being the major etiology.⁶⁻⁹ Nasal fractures are often missed on initial evaluation, especially when there are many more urgent trauma concerns. It is best to perform closed or open reduction of a nasal fracture within the first 2 weeks when it is easiest to avoid more elaborate operations later to correct the disfigurement and nasal airway obstruction. Perform the reduction in children within 3 to 7 days as fracture fixation occurs faster than in adults.¹⁰

Suspect a nasal fracture in the blunt trauma patient with a history of epistaxis, new-onset nasal blockage, or a change in nasal appearance. Determine whether the patient has a prior history of a nasal bone fracture as repeat nasal bone fractures will be more difficult to reduce. An old photograph of the patient may aid this determination. One study revealed that 30% of injured noses had a preexisting nasal deformity.¹¹ At least 48% of the general population has a deviated nasal septum.¹² Physical examination of the blunt trauma patient may demonstrate skin lacerations, nasal tenderness and mobility, internal mucoperichondrial tears, ecchymosis, or a septal hematoma. A septal hematoma must be drained to avoid cartilage necrosis and the subsequent saddle nose deformity. Refer to Chapter 204 regarding the complete details of managing a nasal septal hematoma.

ANATOMY AND PATHOPHYSIOLOGY

The mechanism of injury, force of impact, direction of impact, and history of any prior nasal deformity must be ascertained from the patient in order to understand the potential magnitude of the fracture. If possible, obtain photographic documentation before any attempts at nasal manipulation. The Waters and lateral nasal radiographs will often support the physical findings of a nasal fracture (**Figure 203-2**). Many Surgeons recommend radiographs as part of the medical legal documentation, although many do not agree. Plain radiographs can have a high false-negative rate due to the lack of fine resolution or a high false-positive rate from the misinterpretation of the normal bony sutures.^{13,14} A computed tomography (CT) scan is more sensitive and specific to identify a nasal bone fracture. Unfortunately, its cost and the radiation exposure are significant. A nasal fracture can often be diagnosed based upon the history and the physical examination. Reserve the CT scan for those patients with suspected nasal fractures who may have additional injuries requiring a CT scan.

A bedside ultrasound can be used to evaluate the patient for a nasal fracture (**Figures 203-3 and 203-4**).¹⁵⁻²¹ Use a high-frequency transducer with the smallest footprint available. A clear container containing water or saline can be placed over the patient's nose to

FIGURE 203-2. Radiograph demonstrating a Waters view of a deviated nasal septum and right nasal bone fracture.

get a clearer view using the ultrasound transducer.²² Ultrasound was superior to plain films to assess the lateral nasal walls whereas plain films were superior to assess the nasal dorsum.¹⁵ Ultrasound may become the imaging modality of choice as it has better accuracy than plain films and CT scans.^{16,17}

The direction of the force to fracture the nasal bone is variable. There are several lateral and frontal force injury classifications but no consensus exists.^{9,23,24} One study demonstrated that 66% of nasal fractures were due to lateral forces, 13% were from frontal forces, and 21% were from mixed forces.⁷ This predominance of lateral force fractures is due to several factors.²⁵ It takes more than twice the force, in cadavers, to cause a frontal impact fracture than to cause a lateral impact fracture.

C

FIGURE 203-4. Ultrasonography to assess the nasal pyramid. **A.** Assessment of the patient's right side. **B.** Assessment of the patient's left side. **C.** The normal nasal bone, the slightly hypoechoic nasomaxillary suture, and the frontal process of the maxilla. (Used with permission from Ma OJ, et al: *Ma & Mateer's Emergency Ultrasound*, 3rd ed. New York: McGraw-Hill; 2014.)

Always rule out any associated maxillofacial injuries, especially when the patient presents with ocular hypertelorism and lid lateral-pull laxity.²⁶ Thoroughly evaluate the patient for the presence of other head or neck injuries if they have a nasal fracture. Associated head and neck injuries take priority for management and evaluation as they can result in significant morbidity. Subcutaneous emphysema may be found in nasal trauma cases as well as with simple lamina papyracea fractures and nose blowing. Scleral chemosis, subconjunctival hemorrhage, eyelid edema, periorbital ecchymosis, or subconjunctival hemorrhage may all be associated with a complex facial fracture or an isolated nasal fracture. A history of anosmia indicates a possible cribriform plate fracture. Evaluate the patient for cerebrospinal fluid rhinorrhea and the presence of beta₂-transferrin.⁵ Consider obtaining axial and coronal CT scans of the paranasal sinuses with possible cisternography.

The nose consists of the external nose, the bilateral nasal cavities, and the nasal septum. The external nose consists of the bony upper third, the cartilaginous lower third, and the surrounding soft tissue and skin (**Figure 203-5**). The bony part consists of the paired nasal bones, the frontal processes of the maxillary bones, and the nasal processes of the frontal bones. The inferior nasal bones are thinner than the superior nasal bones. Thus, the lower bony portion is the most common area of the external nose to be fractured.

The cartilaginous components consist of the arched paired upper lateral cartilages and the horseshoe-shaped paired lower lateral cartilages. The former articulates with the cartilaginous septum and nasal bones, while the latter has ligamentous attachments to each other in front of the cartilaginous septum. The lower and upper lateral cartilages articulate with each other and form a crucial part of the nasal valve, the critical control point of nasal resistance and obstruction. Any of these relationships can become dislocated from a traumatic impact and will require repair for an optimal functional and aesthetic outcome. The more lateral sesamoid cartilages are relatively unimportant in these regards.²⁷

The bony nasal septum consists of the perpendicular plate of the ethmoid bone, the vomer, the anterior nasal spine, the maxillary crest, and the palatine bone (**Figure 203-6**). The perpendicular plate of the ethmoid bone is thin except at its articulation with the vomer and cartilaginous septum. **The perpendicular plate of the ethmoid bone is the most common location for a septal fracture.** The quadrangular cartilage of the septum is anteriorly located on the maxillary crest. It can be dislocated into either nostril with a significant force, especially from an inferior direction, and result in nasal airway obstruction.⁹

The inner walls of the nose contain an extensive network of nerves and blood vessels (**Figures 203-7 and 203-8**). These networks form an anastomosis within the walls of the nasal cavity. This is the reason injuries to the nose hurt and bleed so much.

The bony nasal septal fracture is often similar regardless of whether the etiology is a frontal or lateral impact (**Figure 203-9**). It usually begins just posterior to the nasal spine at or just above the maxillary crest. The fracture can progress through this area and straight into the vomer where it curves like a "C" vertically upward and into the perpendicular plate of the ethmoid bone.²⁸

Nasal fractures increase in severity from a unilateral depression without a septal fracture, to a nasal twist or deviation, to a significantly comminuted nasal fracture as the frontal or lateral force of impact increases (**Figure 203-10**). Between these extremes are the moderately severe bilateral fractures with the contralateral side being driven outward and more significantly impacted traumas, such as the previously described C-shaped septal fracture with overriding and interlocked fragments. This latter condition often appears as the classically shortened and twisted nose with tip ptosis from columellar retraction. There is often significant nasal airway obstruction as the quadrangular cartilage telescopes over the perpendicular plate

FIGURE 203-5. Anatomy of the external nasal cartilages. **A.** Frontal view. **B.** Lateral view.

FIGURE 203-6. Anatomy of the nasal septum.

of the ethmoid causing thickening at this point and the appearance of a bilaterally deviated nasal septum.²⁹

The more common lateral force shifts the bony pyramid laterally (**Figure 203-10**) while a frontal impact broadens the nose. “Open book fractures” may occur in pediatric patients due to the open midline suture of the nasal bones. This results in each of the nasal bones being shifted laterally (**Figure 203-11**). Children have fewer nasal fractures because of their smaller and more cartilaginous (i.e., more elastic) noses.^{30,31} Greenstick fractures are more likely in children because of their resilient noses and can be present when it is not apparent externally.^{32,33}

INDICATIONS

Attempt to reduce nasal fractures within the first 3 to 6 hours after the trauma before significant edema develops. Otherwise, perform the reduction 3 to 10 days after the injury when the edema subsides.³⁴ The indications for a closed nasal reduction include unilateral or bilateral nasal bone fractures, with or without a nasal septal

FIGURE 203-7. Nerve supply of the nasal mucosa. **A.** The nasal septum. **B.** The lateral nasal wall.

FIGURE 203-8. Blood supply of the nasal mucosa. **A.** The nasal septum. **B.** The lateral nasal wall.

fracture. Interestingly, one study found that 30% of nasal fractures that underwent closed nasal reduction were still malaligned postoperatively.²⁹ Strongly consider reduction under procedural sedation or general anesthesia.³⁵

CONTRAINDICATIONS

There are no absolute contraindications to nasal fracture reduction as long as the timing, the patient's health status, and associated injuries are considered. The proper approach varies by the extensiveness of the fracture. Open nasal reduction is required for more severe nasal fractures, especially those with C-shaped septal fractures and cartilage telescoping over the perpendicular plate of the ethmoid bone.⁷ Some authors have defined the indications for this more aggressive approach as being a nasal pyramid deviation exceeding one-half of the width of the nasal bridge.²⁹ Consider using an open approach, either during the same setting or within a few days, if deformities persist after closed reduction. Relative indications for the open approach include fracture-dislocations of the caudal septum, open septal fractures, septal hematomas, displaced fractures of the anterior nasal spine, associated alar cartilage deformities, or

recent intranasal surgery. An open approach may be required if an extensive septal deformity exists.⁶ Otherwise, the nasal deformity will be difficult to reduce against the interlocked forces.⁶

EQUIPMENT

- Headlight with light source, or overhead light
- 5 mL syringe
- 27 gauge needle, 1.5 inches long
- 25 gauge spinal needle
- Local anesthetic solution containing 1:100,000 epinephrine
- Oxymetazoline nasal spray
- 4% cocaine, 4 mL
- Other nasal decongestants and anesthetics (Chapter 205 and Table 205-1)
- Atomizer (Table 203-1) (optional)
- Surgical cotton paddies, 0.5 × 2 inches
- Bayonet forceps
- Walsham forceps (Figure 203-12)
- Asch forceps (Figure 203-12)
- Rubber tubing
- Boies nasal fracture elevator (Figure 203-12)
- Killian nasal speculum
- Silastic nasal splints or Goldsmith splints
- Antibiotic-impregnated strip gauze or nasal tampon
- Plaster of Paris splinting/casting material
- 5-0 plain gut suture

FIGURE 203-9. Schematic illustration of a common nasal septal fracture pattern. The fracture proceeds from the area of the maxillary crest, through the vomer, and up into the perpendicular plate of the ethmoid like a backward "C" going up into a "T" as represented by the dashed line.

FIGURE 203-10. Nasal fractures resulting from lateral forces. **A.** Unilateral nasal fracture. **B.** Bilateral nasal fracture. The arrows depict the direction of the force of impact.

FIGURE 203-11. An “open book” nasal fracture resulting from a frontal impact.

- Paper tape, 1 inch wide
- Benzoin solution
- Ultrasound machine
- Ultrasound gel
- High-frequency (10 to 20 MHz) transducer with a small footprint

PATIENT PREPARATION

Explain the procedure, its risks, and benefits to the patient and/or their representative. Significant complications include patient dissatisfaction, the possible need for open reduction within 2 weeks, and formal nasal reconstruction months later. Other potential complications of much lower probability include adverse reactions to the local anesthetics, excessive bleeding, infection, saddle nose deformity, septal perforation, cerebrospinal fluid rhinorrhea, and/or visual disturbances. Almost all of these complications can result from the reduction procedure, but also from the nasal fracture without the reduction attempts. Obtain an informed consent for the procedure.

Place the patient sitting upright in a multiposition procedure chair, or on a stretcher, with the head elevated to decrease blood flow and bleeding. Obtain an objective measure of the degree of lateral displacement. Draw a perpendicular line from the midpoint of the interpupillary line and extending downward to the base of the nasal columella. A point one-third of the way down from the cephalic end is the reference point for any deviation.³⁶ Consider the administration of parenteral analgesics, sedatives, or procedural sedation. Refer to Chapter 159 regarding the details of procedural

TABLE 203-1 Atomizers Currently Available

Name	Manufacturer	Comments
DeVilbiss Model 15 Medical Atomizer	DeVilbiss Healthcare	Adjustable tip Disposable and reusable versions
Enk Fiberoptic Atomizer Kit	Cook Medical	Atomizes through fiberoptic bronchoscope working channel
EZ-Spray	Alcove Medical	Pressure-resistant oxygen tubing Disposable Trigger valve system
LMA MADdy Pediatric Mucosal Atomizer Device	Teleflex	11.4 cm long Attaches to standard syringe Child friendly Comes in various colors and shapes Disposable single use
LMA Bottle MADomizer Atomizer	Teleflex	10 cm long Disposable single-use tips Reusable bottle
LMA MADgic Laryngo-Tracheal Atomizer	Teleflex	21.6 cm long Attaches to standard syringe Disposable single use Flexible tube
LMA MAD Nasal-Intranasal Mucosal Atomizer Device	Teleflex	Attaches to standard syringe Disposable single use

sedation and analgesia. Obtain a prereduction photograph of the patient's face and nose, if possible.

NASAL ANESTHESIA

Anesthetize the nasal mucosa. Insert a nasal speculum. Apply oxy-metazoline nasal spray bilaterally to decongest the nasal mucosa. Use an atomizer (**Table 203-1**) if available to increase the placement of the spray. Place 4 mL of 4% cocaine onto cotton pledgets. Cocaine is a vasoconstrictor, a decongestant, and an anesthetic. Insert the nasal speculum and pack the cocaine-soaked pledgets into the nose using a bayonet forceps (**Figures 203-13**). Ideally, place four pledgets in each nostril at the strategic points of the neurovascular supply (**Figure 203-13**). These areas include the posterior edge of the middle turbinate (to anesthetize and shrink the sphenopalatine ganglion and artery), the anterior to middle turbinate and opposing septum (to anesthetize and shrink the anterior ethmoid nerve and artery), the nasal floor (to anesthetize and shrink the branches of both nerves and arteries), and the mid-septum (to anesthetize and shrink the branches of both nerves and arteries).^{10,27} Allow the cocaine pledgets to remain in the nasal cavity for 10 minutes. Other anesthetics, decongestants, and anesthetic-decongestant combinations can be used depending upon availability. Refer to Chapter 205 for a more complete discussion of topical nasal anesthesia and decongestion.

Inject local anesthetic solution to anesthetize the remainder of the nose. The most commonly used agent is 1% or 2% lidocaine containing 1:100,000 epinephrine.³⁷ Acidosis from the injured tissues can make local anesthesia less effective. The addition of sodium bicarbonate at a 1:10 dilution will counteract the acidosis and lessen the discomfort from the injection.³⁸

Perform the local anesthetic injections intranasally to avoid the added pain of puncturing through the skin (**Figures 203-14 and 203-15**). Infiltrate subcutaneously to anesthetize the external, nasal, infratrochlear, and infraorbital branches of the trigeminal nerve.^{7,8} Insert the needle into the nasal cavity. Infiltrate along the nasal floor to anesthetize the superior alveolar nerve and ganglion. Infiltrate posterior to the inferior and middle turbinates to block the sphenopalatine nerve and ganglion. Allow 10 to 15 minutes for the local anesthetic agent to take effect. Assess the adequacy of the anesthesia

using pinprick of the nasal mucosa. If intranasal injections are performed properly, in a patient who is under procedural sedation and analgesia, the rare but potentially serious complications of using topical cocaine may be avoided. One paper proposed using EMLA (eutectic mixture of local anesthetics) cream externally and cocaine intranasally.³⁹ This has yet to become a broadly accepted technique. The Emergency Physician may not feel comfortable with the technique of intranasal injection and the nerves may be anesthetized percutaneously as described in Chapter 156.⁴⁰

TECHNIQUES

NASAL BONE REDUCTION

Several studies have demonstrated that closed nasal reduction is 80% to 95% successful.^{12,41-46} Measure the distance from the nostril rim to the nasofrontal angle in order to avoid putting the blade in too far (**Figure 203-16A**). Insert one blade of the Asch forceps, one blade of the Walsham forceps, or a Boies nasal fracture elevator into the nostril to the measured distance. Place the instrument against the depressed nasal bone. Apply a gentle upward and outward force while simultaneously applying digital counterpressure to guide the bone into reduction (**Figure 203-16B**). Alternatively, cover the other blade of the Asch or Walsham forceps with rubber tubing so that it can provide counterpressure to the intranasal blade during outward reduction (**Figure 203-17**).¹⁰ Repeat the procedure on the contralateral side if there is a bilateral nasal bone fracture.

NASAL SEPTAL REDUCTION

A nasal septal fracture is often present if bilateral pyramidal fractures exist. **Always reduce the nasal bone fracture(s) before manipulating the septum.** Insert a nasal speculum and determine whether the reduction of the nasal bones results in a straightening of the septum. If not, withdraw the nasal speculum and reduce the septum with the Asch or Walsham forceps (**Figure 203-18**). Insert the forceps with one blade in each nostril. Gently close the blades of the forceps to grasp the septum. Elevate the septum upward and anteriorly to disimpact any interlocked fragments. Reinsert the nasal speculum and visualize the nasal septum. Insert a Boies or Freer elevator under direct visualization and straighten the septum more precisely.

ULTRASOUND-GUIDED REDUCTION

Ultrasound can be used in the diagnosis of a nasal fracture.¹⁵⁻²¹ Use the highest frequency transducer, ideally 20 MHz, as possible.¹⁸ Ultrasound was also found to be useful to assess the positioning of the nasal bones.¹⁹ Ultrasound should be used before the reduction to plan, during the reduction to evaluate, and after the reduction to confirm the reduction. Otherwise, the reduction technique is the same as described above. Interestingly, one study found visual inspection and palpation were just as reliable as ultrasound in confirming the reduction.⁴⁷
